Preface

This book is the official documentation of Postgres Pro Standard. It has been written by the Postgres Pro developers, PostgreSQL community, and other volunteers in parallel to the development of the PostgreSQL and Postgres Pro software. It describes all the functionality that the current version of Postgres Pro officially supports.

To make the large amount of information about Postgres Pro manageable, this book has been organized in several parts. Each part is targeted at a different class of users, or at users in different stages of their Postgres Pro experience:

- **Part I** is an informal introduction for new users.
- **Part II** documents the SQL query language environment, including data types and functions, as well as user-level performance tuning. Every Postgres Pro user should read this.
- **Part III** describes the installation and administration of the server. Everyone who runs a Postgres Pro server, be it for private use or for others, should read this part.
- **Part IV** describes the programming interfaces for Postgres Pro client programs.
- **Part V** contains information for advanced users about the extensibility capabilities of the server. Topics include user-defined data types and functions.
- **Part VI** contains reference information about SQL commands, client and server programs. This part supports the other parts with structured information sorted by command or program.
- **Part VII** contains assorted information that might be of use to Postgres Pro developers.

1. **What Is Postgres Pro Standard?**

Postgres Pro Standard is an object-relational database management system (ORDBMS), developed by Postgres Professional in the Postgres Pro fork of *PostgreSQL*, which is in turn based on *POSTGRES, Version 4.2*, developed at the University of California at Berkeley Computer Science Department. POSTGRES pioneered many concepts that only became available in some commercial database systems much later.

Both PostgreSQL and Postgres Pro Standard support a large part of the SQL standard and offer many modern features:

- complex queries
- foreign keys
- triggers
- updatable views
- transactional integrity
- multiversion concurrency control

Besides, PostgreSQL and Postgres Pro can be extended by the user in many ways, for example by adding new

- data types
- functions
- operators
- aggregate functions
- index methods
- procedural languages

2. **Difference between Postgres Pro Standard and PostgreSQL**

Postgres Pro provides the most actual PostgreSQL version with some additional patches applied and extensions added. It includes new features developed by Postgres Professional, as well as third-party
patches already accepted by the PostgreSQL community for the upcoming PostgreSQL versions. Postgres Pro Standard users thus have early access to important features and fixes.

**Note**

Postgres Pro Standard is provided under the following license: [https://postgrespro.com/products/postgrespro/eula](https://postgrespro.com/products/postgrespro/eula). Make sure to review the license terms before downloading Postgres Pro Standard.

Postgres Pro Standard provides the following enhancements over PostgreSQL:

- Improved deadlock detection mechanism that does not cause performance degradation.
- Better planning speed and accuracy for various query types.
- Reduced memory consumption in complex queries that involve multiple tables.
- Displaying planning time in the output of the `auto_explain` module.
- NUL byte replacement with the specified ASCII code while loading data using the `COPY FROM` command. (See `nul_byte_replacement_on_import` parameter description.)
- ICU collation support on all platforms to provide platform-independent sort for various locales. By default, the `icu` collation provider is used for all locales except `C` and `POSIX`. (See Section 22.2.2.)
- `PTRACK` implementation, which enables `pg_probackup` to track page changes on the fly when creating incremental backups.
- Support for reading `pg_control` of previous PostgreSQL/Postgres Pro major versions by `pgpro_controldata`.
- Cluster compatibility verification, which allows you to determine whether the current Postgres Pro version is compatible with the specified cluster and identify all parameters that can affect the compatibility without starting the cluster. (See `pgpro_controldata` and `--Z` option of `postgres`.)
- Changing the `restore_command` parameter without restarting the server.
- Improvements for command-line editing using WinEditLine in the Windows version of `psql`, including autocomplete support in `psql` console and changing the `psql` default encoding to UTF-8.
- Unified structure of binary installation packages across all Linux distributions, which facilitates migration between them and allows to install different PostgreSQL-based products side by side, without any conflicts. (See Chapter 16.)
- Advanced authentication policies that provide effective password management and access control. (See `CREATE PROFILE` and `ALTER ROLE`.)
- Built-in data security mechanisms that enable sanitizing an object by filling it with zeroes before deletion. Zeroing can be done before purging files in external memory and removing outdated row versions (page vacuum), freeing RAM, and deleting or overwriting WAL files. (Certified edition only.)

Postgres Pro Standard also includes the following additional modules:

- `dump_stat` module that allows to save and restore database statistics when dumping/restoring the database.
- `fasttrun` module that provides transaction-unsafe function to truncate temporary tables without growing `pg_class` size.
- `fulleq` module that provides additional equivalence operator for compatibility with Microsoft SQL Server.
- `hunspell-dict` module that provides dictionaries for several languages.
- `jsquery` module that provides a specific language for effective index-supported querying of JSONB data.
- `mamonsu` monitoring service, which is implemented as a Zabbix agent.
- `mchar` module that provides additional data type for compatibility with Microsoft SQL Server.
- `online_analyze` module that provides a set of changes to immediately update statistics after `INSERT`, `UPDATE`, `DELETE` or `SELECT INTO` operations applied for affected tables.
- `pgbouncer` connection pooler.
- `pg_integrity_check` module that calculates checksums for controlled files. (Certified edition only.)
• **pg_pathman** module that provides optimized partitioning mechanism and functions to manage partitions. Starting from Postgres Pro 12, using pg_pathman is not recommended. Use vanilla declarative partitioning instead, as described in Section 5.11.

• **pg_proaudit** extension that enables detailed logging of various security events.

• **pg_probackup**, a backup and recovery manager.

• **pgpro_controldata**, an application to display control information of a PostgreSQL/Postgres Pro database cluster and compatibility information for a cluster and/or server.

• **pgpro_pwr** extension that enables you to generate workload reports, which help to discover most resource-intensive activities in your database.

• **pgpro_stats** extension that combines tracking execution statistics of SQL statements and calculating wait event statistics.

• **pg_query_state** module that enables you to get the current state of query execution for a backend.

• **pg_repack** utility for reorganizing tables.

• **pg_tsparser** module, which is an alternative text search parser.

• **pg_variables** module that provides functions for working with variables of various types.

• **plantuner** module that provides hints for the planner to disable or enable indexes for query execution.

• **shared_ispell** module that enables storing dictionaries in shared memory.

Postgres Pro Standard releases follow PostgreSQL releases, though sometimes occur more frequently. The Postgres Pro Standard versioning scheme is based on the PostgreSQL one and has an additional decimal place.

### 3. A Brief History of PostgreSQL

The object-relational database management system now known as PostgreSQL is derived from the POSTGRES package written at the University of California at Berkeley. With over two decades of development behind it, PostgreSQL is now the most advanced open-source database available anywhere.

#### 3.1. The Berkeley POSTGRES Project

The POSTGRES project, led by Professor Michael Stonebraker, was sponsored by the Defense Advanced Research Projects Agency (DARPA), the Army Research Office (ARO), the National Science Foundation (NSF), and ESL, Inc. The implementation of POSTGRES began in 1986. The initial concepts for the system were presented in ston86, and the definition of the initial data model appeared in rowe87. The design of the rule system at that time was described in ston87a. The rationale and architecture of the storage manager were detailed in ston87b.

POSTGRES has undergone several major releases since then. The first “demoware” system became operational in 1987 and was shown at the 1988 ACM-SIGMOD Conference. Version 1, described in ston90a, was released to a few external users in June 1989. In response to a critique of the first rule system (ston89), the rule system was redesigned (ston90b), and Version 2 was released in June 1990 with the new rule system. Version 3 appeared in 1991 and added support for multiple storage managers, an improved query executor, and a rewritten rule system. For the most part, subsequent releases until Postgres95 (see below) focused on portability and reliability.

POSTGRES has been used to implement many different research and production applications. These include: a financial data analysis system, a jet engine performance monitoring package, an asteroid tracking database, a medical information database, and several geographic information systems. POSTGRES has also been used as an educational tool at several universities. Finally, Illustra Information Technologies (later merged into Informix, which is now owned by IBM) picked up the code and commercialized it. In late 1992, POSTGRES became the primary data manager for the Sequoia 2000 scientific computing project.

The size of the external user community nearly doubled during 1993. It became increasingly obvious that maintenance of the prototype code and support was taking up large amounts of time that should have been devoted to database research. In an effort to reduce this support burden, the Berkeley POSTGRES project officially ended with Version 4.2.
3.2. Postgres95

In 1994, Andrew Yu and Jolly Chen added an SQL language interpreter to POSTGRES. Under a new name, Postgres95 was subsequently released to the web to find its own way in the world as an open-source descendant of the original POSTGRES Berkeley code.

Postgres95 code was completely ANSI C and trimmed in size by 25%. Many internal changes improved performance and maintainability. Postgres95 release 1.0.x ran about 30–50% faster on the Wisconsin Benchmark compared to POSTGRES, Version 4.2. Apart from bug fixes, the following were the major enhancements:

- The query language PostQUEL was replaced with SQL (implemented in the server). (Interface library libpq was named after PostQUEL.) Subqueries were not supported until PostgreSQL (see below), but they could be imitated in Postgres95 with user-defined SQL functions. Aggregate functions were re-implemented. Support for the \texttt{GROUP BY} query clause was also added.

- A new program (psql) was provided for interactive SQL queries, which used GNU Readline. This largely superseded the old monitor program.

- A new front-end library, \texttt{libpgtcl}, supported Tcl-based clients. A sample shell, \texttt{pgtclsh}, provided new Tcl commands to interface Tcl programs with the Postgres95 server.

- The large-object interface was overhauled. The inversion large objects were the only mechanism for storing large objects. (The inversion file system was removed.)

- The instance-level rule system was removed. Rules were still available as rewrite rules.

- A short tutorial introducing regular SQL features as well as those of Postgres95 was distributed with the source code

- GNU make (instead of BSD make) was used for the build. Also, Postgres95 could be compiled with an unpatched GCC (data alignment of doubles was fixed).

3.3. PostgreSQL

By 1996, it became clear that the name “Postgres95” would not stand the test of time. We chose a new name, PostgreSQL, to reflect the relationship between the original POSTGRES and the more recent versions with SQL capability. At the same time, we set the version numbering to start at 6.0, putting the numbers back into the sequence originally begun by the Berkeley POSTGRES project.

Many people continue to refer to PostgreSQL as “Postgres” (now rarely in all capital letters) because of tradition or because it is easier to pronounce. This usage is widely accepted as a nickname or alias.

The emphasis during development of Postgres95 was on identifying and understanding existing problems in the server code. With PostgreSQL, the emphasis has shifted to augmenting features and capabilities, although work continues in all areas.

4. Conventions

The following conventions are used in the synopsis of a command: brackets ([ and ]) indicate optional parts. (In the synopsis of a Tcl command, question marks (?) are used instead, as is usual in Tcl.) Braces ({} and {}) and vertical lines (|) indicate that you must choose one alternative. Dots (…) mean that the preceding element can be repeated.

Where it enhances the clarity, SQL commands are preceded by the prompt =>, and shell commands are preceded by the prompt $. Normally, prompts are not shown, though.

An administrator is generally a person who is in charge of installing and running the server. A user could be anyone who is using, or wants to use, any part of the Postgres Pro system. These terms should not be interpreted too narrowly; this book does not have fixed presumptions about system administration procedures.
5. Bug Reporting Guidelines

When you find a bug in Postgres Pro we want to hear about it. Your bug reports play an important part in making Postgres Pro more reliable because even the utmost care cannot guarantee that every part of Postgres Pro will work on every platform under every circumstance.

The following suggestions are intended to assist you in forming bug reports that can be handled in an effective fashion. No one is required to follow them but doing so tends to be to everyone’s advantage.

5.1. Identifying Bugs

Before you report a bug, please read and re-read the documentation to verify that you can really do whatever it is you are trying. If it is not clear from the documentation whether you can do something or not, please report that too; it is a bug in the documentation. If it turns out that a program does something different from what the documentation says, that is a bug. That might include, but is not limited to, the following circumstances:

- A program terminates with a fatal signal or an operating system error message that would point to a problem in the program. (A counterexample might be a “disk full” message, since you have to fix that yourself.)
- A program produces the wrong output for any given input.
- A program refuses to accept valid input (as defined in the documentation).
- A program accepts invalid input without a notice or error message. But keep in mind that your idea of invalid input might be our idea of an extension or compatibility with traditional practice.
- Postgres Pro fails to install according to the instructions on supported platforms.

Here “program” refers to any executable, not only the backend process.

Being slow or resource-hogging is not necessarily a bug. Failing to comply to the SQL standard is not necessarily a bug either, unless compliance for the specific feature is explicitly claimed.

5.2. What to Report

When reporting a bug, make sure to state all the facts. Each bug report should contain the following items:

- The exact sequence of steps from program start-up necessary to reproduce the problem. This should be self-contained; it is not enough to send in a bare SELECT statement without the preceding CREATE TABLE and INSERT statements, if the output should depend on the data in the tables.

The best format for a test case for SQL-related problems is a file that can be run through the psql frontend that shows the problem. (Be sure to not have anything in your ~/.psqlrc start-up file.) An easy way to create this file is to use pg_dump to dump out the table declarations and data needed to set the scene, then add the problem query. You are encouraged to minimize the size of your example, but this is not absolutely necessary. If the bug is reproducible, we will find it either way.

If your application uses some other client interface, such as PHP, then please try to isolate the offending queries.

- The output you got. If there is an error message, show it. If the program terminates with an operating system error, say which. If nothing at all happens, say so. Even if the result of your test case is a program crash or otherwise obvious it might not happen on our platform. The easiest thing is to copy the output from the terminal, if possible.

Note

If you are reporting an error message, please obtain the most verbose form of the message. In psql, say \set VERBOSITY verbose beforehand. If you are extracting the message from the
server log, set the run-time parameter `log_error_verbosity` to `verbose` so that all details are logged.

**Note**

In case of fatal errors, the error message reported by the client might not contain all the information available. Please also look at the log output of the database server.

- The output you expect is very important to state. Please provide the expected output, if applicable.
- Any command line options and other start-up options, including any relevant environment variables or configuration files that you changed from the default.
- Anything you did at all differently from the installation instructions.
- The Postgres Pro version. You can run the command `SELECT pgpro_version();` to find out the version of the server you are connected to. Most executable programs also support a `--version` option; at least `postgres --version` and `psql --version` should work.
- Platform information. This includes the kernel name and version, C library, processor, memory information, and so on.

### 5.3. Where to Report Bugs

In general, send bug reports to our support email address at `<bugs@postgrespro.ru>`. You are requested to use a descriptive subject for your email message, perhaps parts of the error message.

Do not send bug reports specific to Postgres Pro to the PostgreSQL support email address, as Postgres Pro is not supported by the PostgreSQL community. But you can send reports to `<pgsql-bugs@lists.postgresql.org>` for any bugs related to PostgreSQL.

Even if your bug is not specific to Postgres Pro, do not send bug reports to any of the user mailing lists, such as `<pgsql-sql@lists.postgresql.org>` or `<pgsql-general@lists.postgresql.org>`. These mailing lists are for answering user questions, and their subscribers normally do not wish to receive bug reports. More importantly, they are unlikely to fix them.

Also, please do not send reports to the developers' mailing list `<pgsql-hackers@lists.postgresql.org>`. This list is for discussing the development of PostgreSQL, and it would be nice if the community could keep the bug reports separate. The community might choose to take up a discussion about your bug report on `pgsql-hackers`, if the PostgreSQL-related problem needs more review.
Part I. Tutorial

Welcome to the Postgres Pro Tutorial. The following few chapters are intended to give a simple introduction to Postgres Pro, relational database concepts, and the SQL language to those who are new to any one of these aspects. We only assume some general knowledge about how to use computers. No particular Unix or programming experience is required. This part is mainly intended to give you some hands-on experience with important aspects of the Postgres Pro system. It makes no attempt to be a complete or thorough treatment of the topics it covers.

After you have worked through this tutorial you might want to move on to reading Part II to gain a more formal knowledge of the SQL language, or Part IV for information about developing applications for Postgres Pro. When learning SQL, you can use the demo database described in Appendix K. Those who set up and manage their own server should also read Part III.
Chapter 1. Getting Started

1.1. Installation

Before you can use Postgres Pro you need to install it, of course. It is possible that Postgres Pro is already installed at your site, either because it was included in your operating system distribution or because the system administrator already installed it. If that is the case, you should obtain information from the operating system documentation or your system administrator about how to access Postgres Pro.

If you are installing Postgres Pro Standard yourself, then see instructions on installation (Chapter 16), and return to this guide when the installation is complete. Be sure to follow closely the section about setting up the appropriate environment variables.

If your site administrator has not set things up in the default way, you might have some more work to do. For example, if the database server machine is a remote machine, you will need to set the `PGHOST` environment variable to the name of the database server machine. The environment variable `PGPORT` might also have to be set. The bottom line is this: if you try to start an application program and it complains that it cannot connect to the database, you should consult your site administrator or, if that is you, the documentation to make sure that your environment is properly set up. If you did not understand the preceding paragraph then read the next section.

1.2. Architectural Fundamentals

Before we proceed, you should understand the basic Postgres Pro system architecture. Understanding how the parts of Postgres Pro interact will make this chapter somewhat clearer.

In database jargon, Postgres Pro uses a client/server model. A Postgres Pro session consists of the following cooperating processes (programs):

- A server process, which manages the database files, accepts connections to the database from client applications, and performs database actions on behalf of the clients. The database server program is called `postgres`.
- The user's client (frontend) application that wants to perform database operations. Client applications can be very diverse in nature: a client could be a text-oriented tool, a graphical application, a web server that accesses the database to display web pages, or a specialized database maintenance tool. Some client applications are supplied with the Postgres Pro distribution; most are developed by users.

As is typical of client/server applications, the client and the server can be on different hosts. In that case they communicate over a TCP/IP network connection. You should keep this in mind, because the files that can be accessed on a client machine might not be accessible (or might only be accessible using a different file name) on the database server machine.

The Postgres Pro server can handle multiple concurrent connections from clients. To achieve this it starts ("forks") a new process for each connection. From that point on, the client and the new server process communicate without intervention by the original `postgres` process. Thus, the supervisor server process is always running, waiting for client connections, whereas client and associated server processes come and go. (All of this is of course invisible to the user. We only mention it here for completeness.)

1.3. Creating a Database

The first test to see whether you can access the database server is to try to create a database. A running Postgres Pro server can manage many databases. Typically, a separate database is used for each project or for each user.

Possibly, your site administrator has already created a database for your use. In that case you can omit this step and skip ahead to the next section.

To create a new database, in this example named `mydb`, you use the following command:
Getting Started

```sh
$ createdb mydb
```

If this produces no response then this step was successful and you can skip over the remainder of this section.

If you see a message similar to:

```
createdb: command not found
```

then Postgres Pro was not installed properly. Either it was not installed at all or your shell's search path was not set to include it. Try calling the command with an absolute path instead:

```sh
$ /usr/local/pgsql/bin/createdb mydb
```

The path at your site might be different. Contact your site administrator or check the installation instructions to correct the situation.

Another response could be this:

```
createdb: error: connection to server on socket "/tmp/.s.PGSQL.5432" failed: No such file or directory
```

Is the server running locally and accepting connections on that socket?

This means that the server was not started, or it is not listening where `createdb` expects to contact it. Again, check the installation instructions or consult the administrator.

Another response could be this:

```
createdb: error: connection to server on socket "/tmp/.s.PGSQL.5432" failed: FATAL: role "joe" does not exist
```

where your own login name is mentioned. This will happen if the administrator has not created a Postgres Pro user account for you. (Postgres Pro user accounts are distinct from operating system user accounts.) If you are the administrator, see Chapter 20 for help creating accounts. You will need to become the operating system user under which Postgres Pro was installed (usually `postgres`) to create the first user account. It could also be that you were assigned a Postgres Pro user name that is different from your operating system user name; in that case you need to use the `-U` switch or set the `PGUSER` environment variable to specify your Postgres Pro user name.

If you have a user account but it does not have the privileges required to create a database, you will see the following:

```
createdb: error: database creation failed: ERROR: permission denied to create database
```

Not every user has authorization to create new databases. If Postgres Pro refuses to create databases for you then the site administrator needs to grant you permission to create databases. Consult your site administrator if this occurs. If you installed Postgres Pro yourself then you should log in for the purposes of this tutorial under the user account that you started the server as.

You can also create databases with other names. Postgres Pro allows you to create any number of databases at a given site. Database names must have an alphabetic first character and are limited to 63 bytes in length. A convenient choice is to create a database with the same name as your current user name. Many tools assume that database name as the default, so it can save you some typing. To create that database, simply type:

```sh
$ createdb
```

If you do not want to use your database anymore you can remove it. For example, if you are the owner (creator) of the database `mydb`, you can destroy it using the following command:

```sh
$ dropdb mydb
```

---

1 As an explanation for why this works: Postgres Pro user names are separate from operating system user accounts. When you connect to a database, you can choose what Postgres Pro user name to connect as; if you don't, it will default to the same name as your current operating system account. As it happens, there will always be a Postgres Pro user account that has the same name as the operating system user that started the server, and it also happens that that user always has permission to create databases. Instead of logging in as that user you can also specify the `-U` option everywhere to select a Postgres Pro user name to connect as.
(For this command, the database name does not default to the user account name. You always need to specify it.) This action physically removes all files associated with the database and cannot be undone, so this should only be done with a great deal of forethought.

More about `createdb` and `dropdb` can be found in `createdb` and `dropdb` respectively.

1.4. Accessing a Database

Once you have created a database, you can access it by:

- Running the Postgres Pro interactive terminal program, called `psql`, which allows you to interactively enter, edit, and execute SQL commands.
- Using an existing graphical frontend tool like pgAdmin or an office suite with ODBC or JDBC support to create and manipulate a database. These possibilities are not covered in this tutorial.
- Writing a custom application, using one of the several available language bindings. These possibilities are discussed further in Part IV.

You probably want to start up `psql` to try the examples in this tutorial. It can be activated for the `mydb` database by typing the command:

```
$ psql mydb
```

If you do not supply the database name then it will default to your user account name. You already discovered this scheme in the previous section using `createdb`.

In `psql`, you will be greeted with the following message:

```
psql (14.1.1)
Type "help" for help.

mydb=>
```

The last line could also be:

```
mydb=#
```

That would mean you are a database superuser, which is most likely the case if you installed the Postgres Pro instance yourself. Being a superuser means that you are not subject to access controls. For the purposes of this tutorial that is not important.

If you encounter problems starting `psql` then go back to the previous section. The diagnostics of `createdb` and `psql` are similar, and if the former worked the latter should work as well.

The last line printed out by `psql` is the prompt, and it indicates that `psql` is listening to you and that you can type SQL queries into a work space maintained by `psql`. Try out these commands:

```
mydb=> SELECT pgpro_version();
version
-------------------------
PostgresPro 14.1.1 on x86_64-pc-linux-gnu, compiled by gcc (Debian 4.9.2-10) 4.9.2, 64-bit
(1 row)
```

```
mydb=> SELECT current_date;
date
----------
2016-01-07
(1 row)
```

```
mydb=> SELECT 2 + 2;
?column?
----------
4
```
The psql program has a number of internal commands that are not SQL commands. They begin with the backslash character, "\". For example, you can get help on the syntax of various Postgres Pro SQL commands by typing:

mydb=> \h

To get out of psql, type:

mydb=> \q

and psql will quit and return you to your command shell. (For more internal commands, type \? at the psql prompt.) The full capabilities of psql are documented in psql. In this tutorial we will not use these features explicitly, but you can use them yourself when it is helpful.
Chapter 2. The SQL Language

2.1. Introduction

This chapter provides an overview of how to use SQL to perform simple operations. This tutorial is only intended to give you an introduction and is in no way a complete tutorial on SQL. Numerous books have been written on SQL, including melt93 and date97. You should be aware that some Postgres Pro language features are extensions to the standard.

In the examples that follow, we assume that you have created a database named mydb, as described in the previous chapter, and have been able to start psql.

2.2. Concepts

Postgres Pro is a relational database management system (RDBMS). That means it is a system for managing data stored in relations. Relation is essentially a mathematical term for table. The notion of storing data in tables is so commonplace today that it might seem inherently obvious, but there are a number of other ways of organizing databases. Files and directories on Unix-like operating systems form an example of a hierarchical database. A more modern development is the object-oriented database.

Each table is a named collection of rows. Each row of a given table has the same set of named columns, and each column is of a specific data type. Whereas columns have a fixed order in each row, it is important to remember that SQL does not guarantee the order of the rows within the table in any way (although they can be explicitly sorted for display).

Tables are grouped into databases, and a collection of databases managed by a single Postgres Pro server instance constitutes a database cluster.

2.3. Creating a New Table

You can create a new table by specifying the table name, along with all column names and their types:

```
CREATE TABLE weather (  
    city              varchar(80),  
    temp_lo           int,           -- low temperature  
    temp_hi           int,           -- high temperature  
    prcp              real,          -- precipitation  
    date              date           
);  
```

You can enter this into psql with the line breaks. psql will recognize that the command is not terminated until the semicolon.

White space (i.e., spaces, tabs, and newlines) can be used freely in SQL commands. That means you can type the command aligned differently than above, or even all on one line. Two dashes ("--") introduce comments. Whatever follows them is ignored up to the end of the line. SQL is case insensitive about key words and identifiers, except when identifiers are double-quoted to preserve the case (not done above).

`varchar(80)` specifies a data type that can store arbitrary character strings up to 80 characters in length. `int` is the normal integer type. `real` is a type for storing single precision floating-point numbers. `date` should be self-explanatory. (Yes, the column of type `date` is also named `date`. This might be convenient or confusing — you choose.)

Postgres Pro supports the standard SQL types `int`, `smallint`, `real`, `double precision`, `char(N)`, `varchar(N)`, `date`, `time`, `timestamp`, and `interval`, as well as other types of general utility and a rich set of geometric types. Postgres Pro can be customized with an arbitrary number of user-defined data types. Consequently, type names are not key words in the syntax, except where required to support special cases in the SQL standard.
The second example will store cities and their associated geographical location:

```sql
CREATE TABLE cities (
    name            varchar(80),
    location        point
);  
```

The `point` type is an example of a Postgres Pro-specific data type.

Finally, it should be mentioned that if you don't need a table any longer or want to recreate it differently you can remove it using the following command:

```sql
DROP TABLE tablename;  
```

### 2.4. Populating a Table With Rows

The `INSERT` statement is used to populate a table with rows:

```sql
INSERT INTO weather VALUES ('San Francisco', 46, 50, 0.25, '1994-11-27');  
```

Note that all data types use rather obvious input formats. Constants that are not simple numeric values usually must be surrounded by single quotes (`'`), as in the example. The `date` type is actually quite flexible in what it accepts, but for this tutorial we will stick to the unambiguous format shown here.

The `point` type requires a coordinate pair as input, as shown here:

```sql
INSERT INTO cities VALUES ('San Francisco', '(-194.0, 53.0)');  
```

The syntax used so far requires you to remember the order of the columns. An alternative syntax allows you to list the columns explicitly:

```sql
INSERT INTO weather (city, temp_lo, temp_hi, prcp, date)
    VALUES ('San Francisco', 43, 57, 0.0, '1994-11-29');  
```

You can list the columns in a different order if you wish or even omit some columns, e.g., if the precipitation is unknown:

```sql
INSERT INTO weather (date, city, temp_hi, temp_lo)
    VALUES ('1994-11-29', 'Hayward', 54, 37);  
```

Many developers consider explicitly listing the columns better style than relying on the order implicitly.

Please enter all the commands shown above so you have some data to work with in the following sections.

You could also have used `COPY` to load large amounts of data from flat-text files. This is usually faster because the `COPY` command is optimized for this application while allowing less flexibility than `INSERT`. An example would be:

```sql
COPY weather FROM '/home/user/weather.txt';  
```

where the file name for the source file must be available on the machine running the backend process, not the client, since the backend process reads the file directly. You can read more about the `COPY` command in `COPY`.

### 2.5. Querying a Table

To retrieve data from a table, the table is `queried`. An SQL `SELECT` statement is used to do this. The statement is divided into a select list (the part that lists the columns to be returned), a table list (the part that lists the tables from which to retrieve the data), and an optional qualification (the part that specifies any restrictions). For example, to retrieve all the rows of table `weather`, type:

```sql
SELECT * FROM weather;  
```

Here `*` is a shorthand for “all columns”. So the same result would be had with:

---

1 While `SELECT *` is useful for off-the-cuff queries, it is widely considered bad style in production code, since adding a column to the table would change the results.
The SQL Language

```
SELECT city, temp_lo, temp_hi, prcp, date FROM weather;
```

The output should be:

<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
<td>0.25</td>
<td>1994-11-27</td>
</tr>
<tr>
<td>San Francisco</td>
<td>43</td>
<td>57</td>
<td>0</td>
<td>1994-11-29</td>
</tr>
<tr>
<td>Hayward</td>
<td>37</td>
<td>54</td>
<td></td>
<td>1994-11-29</td>
</tr>
</tbody>
</table>

(3 rows)

You can write expressions, not just simple column references, in the select list. For example, you can do:

```
SELECT city, (temp_hi+temp_lo)/2 AS temp_avg, date FROM weather;
```

This should give:

<table>
<thead>
<tr>
<th>city</th>
<th>temp_avg</th>
<th>date</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
<td>48</td>
<td>1994-11-27</td>
</tr>
<tr>
<td>San Francisco</td>
<td>50</td>
<td>1994-11-29</td>
</tr>
<tr>
<td>Hayward</td>
<td>45</td>
<td>1994-11-29</td>
</tr>
</tbody>
</table>

(3 rows)

Notice how the AS clause is used to relabel the output column. (The AS clause is optional.)

A query can be “qualified” by adding a WHERE clause that specifies which rows are wanted. The WHERE clause contains a Boolean (truth value) expression, and only rows for which the Boolean expression is true are returned. The usual Boolean operators (AND, OR, and NOT) are allowed in the qualification. For example, the following retrieves the weather of San Francisco on rainy days:

```
SELECT * FROM weather
WHERE city = 'San Francisco' AND prcp > 0.0;
```

Result:

<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
<td>0.25</td>
<td>1994-11-27</td>
</tr>
</tbody>
</table>

(1 row)

You can request that the results of a query be returned in sorted order:

```
SELECT * FROM weather
ORDER BY city;
```

<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hayward</td>
<td>37</td>
<td>54</td>
<td></td>
<td>1994-11-29</td>
</tr>
<tr>
<td>San Francisco</td>
<td>43</td>
<td>57</td>
<td>0</td>
<td>1994-11-29</td>
</tr>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
<td>0.25</td>
<td>1994-11-27</td>
</tr>
</tbody>
</table>

In this example, the sort order isn't fully specified, and so you might get the San Francisco rows in either order. But you'd always get the results shown above if you do:

```
SELECT * FROM weather
ORDER BY city, temp_lo;
```

You can request that duplicate rows be removed from the result of a query:

```
SELECT DISTINCT city
FROM weather;
```

<table>
<thead>
<tr>
<th>city</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hayward</td>
</tr>
<tr>
<td>San Francisco</td>
</tr>
</tbody>
</table>

8
Here again, the result row ordering might vary. You can ensure consistent results by using `DISTINCT` and `ORDER BY` together:

```sql
SELECT DISTINCT city
FROM weather
ORDER BY city;
```

### 2.6. Joins Between Tables

Thus far, our queries have only accessed one table at a time. Queries can access multiple tables at once, or access the same table in such a way that multiple rows of the table are being processed at the same time. Queries that access multiple tables (or multiple instances of the same table) at one time are called **join** queries. They combine rows from one table with rows from a second table, with an expression specifying which rows are to be paired. For example, to return all the weather records together with the location of the associated city, the database needs to compare the `city` column of each row of the `weather` table with the `name` column of all rows in the `cities` table, and select the pairs of rows where these values match. This would be accomplished by the following query:

```sql
SELECT * FROM weather JOIN cities ON city = name;
```

<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
<th>name</th>
<th>location</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
<td>0.25</td>
<td>1994-11-27</td>
<td>San Francisco</td>
<td>(-194,53)</td>
</tr>
<tr>
<td>San Francisco</td>
<td>43</td>
<td>57</td>
<td>0</td>
<td>1994-11-29</td>
<td>San Francisco</td>
<td>(-194,53)</td>
</tr>
</tbody>
</table>

Observe two things about the result set:

- There is no result row for the city of Hayward. This is because there is no matching entry in the `cities` table for Hayward, so the join ignores the unmatched rows in the `weather` table. We will see shortly how this can be fixed.

- There are two columns containing the city name. This is correct because the lists of columns from the `weather` and `cities` tables are concatenated. In practice this is undesirable, though, so you will probably want to list the output columns explicitly rather than using `*`:

```sql
SELECT city, temp_lo, temp_hi, prcp, date, location
FROM weather JOIN cities ON city = name;
```

Since the columns all had different names, the parser automatically found which table they belong to. If there were duplicate column names in the two tables you'd need to **qualify** the column names to show which one you meant, as in:

```sql
SELECT weather.city, weather.temp_lo, weather.temp_hi,
       weather.prcp, weather.date, cities.location
FROM weather JOIN cities ON weather.city = cities.name;
```

It is widely considered good style to qualify all column names in a join query, so that the query won’t fail if a duplicate column name is later added to one of the tables.

Join queries of the kind seen thus far can also be written in this form:

```sql
SELECT *
FROM weather, cities
WHERE city = name;
```

This syntax pre-dates the `JOIN/ON` syntax, which was introduced in SQL-92. The tables are simply listed in the `FROM` clause, and the comparison expression is added to the `WHERE` clause. The results from this older...
implicit syntax and the newer explicit JOIN/ON syntax are identical. But for a reader of the query, the explicit syntax makes its meaning easier to understand: The join condition is introduced by its own keyword whereas previously the condition was mixed into the WHERE clause together with other conditions.

Now we will figure out how we can get the Hayward records back in. What we want the query to do is to scan the weather table and for each row to find the matching cities row(s). If no matching row is found we want some “empty values” to be substituted for the cities table’s columns. This kind of query is called an outer join. (The joins we have seen so far are inner joins.) The command looks like this:

```
SELECT * 
FROM weather LEFT OUTER JOIN cities ON weather.city = cities.name;
```

<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
<th>name</th>
<th>location</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hayward</td>
<td>37</td>
<td>54</td>
<td>0</td>
<td>1994-11-29</td>
<td></td>
<td></td>
</tr>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
<td>0.25</td>
<td>1994-11-27</td>
<td>San Francisco</td>
<td>(-194,53)</td>
</tr>
<tr>
<td>San Francisco</td>
<td>43</td>
<td>57</td>
<td>0</td>
<td>1994-11-29</td>
<td>San Francisco</td>
<td>(-194,53)</td>
</tr>
</tbody>
</table>

(3 rows)

This query is called a left outer join because the table mentioned on the left of the join operator will have each of its rows in the output at least once, whereas the table on the right will only have those rows output that match some row of the left table. When outputting a left-table row for which there is no right-table match, empty (null) values are substituted for the right-table columns.

**Exercise:** There are also right outer joins and full outer joins. Try to find out what those do.

We can also join a table against itself. This is called a self join. As an example, suppose we wish to find all the weather records that are in the temperature range of other weather records. So we need to compare the temp_lo and temp_hi columns of each weather row to the temp_lo and temp_hi columns of all other weather rows. We can do this with the following query:

```
SELECT w1.city, w1.temp_lo AS low, w1.temp_hi AS high, 
      w2.city, w2.temp_lo AS low, w2.temp_hi AS high 
FROM weather w1 JOIN weather w2 
  ON w1.temp_lo < w2.temp_lo AND w1.temp_hi > w2.temp_hi;
```

<table>
<thead>
<tr>
<th>city</th>
<th>low</th>
<th>high</th>
<th>city</th>
<th>low</th>
<th>high</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
<td>43</td>
<td>57</td>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
</tr>
<tr>
<td>Hayward</td>
<td>37</td>
<td>54</td>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
</tr>
</tbody>
</table>

(2 rows)

Here we have relabeled the weather table as w1 and w2 to be able to distinguish the left and right side of the join. You can also use these kinds of aliases in other queries to save some typing, e.g.:

```
SELECT * 
FROM weather w JOIN cities c ON w.city = c.name;
```

You will encounter this style of abbreviating quite frequently.

### 2.7. Aggregate Functions

Like most other relational database products, Postgres Pro supports aggregate functions. An aggregate function computes a single result from multiple input rows. For example, there are aggregates to compute the count, sum, avg (average), max (maximum) and min (minimum) over a set of rows.

As an example, we can find the highest low-temperature reading anywhere with:

```
SELECT max(temp_lo) FROM weather;
```

```
max
46
```
If we wanted to know what city (or cities) that reading occurred in, we might try:

```sql
SELECT city FROM weather WHERE temp_lo = max(temp_lo);
```

but this will not work since the aggregate `max` cannot be used in the `WHERE` clause. (This restriction exists because the `WHERE` clause determines which rows will be included in the aggregate calculation; so obviously it has to be evaluated before aggregate functions are computed.) However, as is often the case the query can be restated to accomplish the desired result, here by using a subquery:

```sql
SELECT city FROM weather
    WHERE temp_lo = (SELECT max(temp_lo) FROM weather);
```

```
San Francisco
```

This is OK because the subquery is an independent computation that computes its own aggregate separately from what is happening in the outer query.

Aggregates are also very useful in combination with `GROUP BY` clauses. For example, we can get the maximum low temperature observed in each city with:

```sql
SELECT city, max(temp_lo)
FROM weather
GROUP BY city;
```

```
<table>
<thead>
<tr>
<th>city</th>
<th>max</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hayward</td>
<td>37</td>
</tr>
<tr>
<td>San Francisco</td>
<td>46</td>
</tr>
</tbody>
</table>
```

which gives us one output row per city. Each aggregate result is computed over the table rows matching that city. We can filter these grouped rows using `HAVING`:

```sql
SELECT city, max(temp_lo)
FROM weather
GROUP BY city
HAVING max(temp_lo) < 40;
```

```
<table>
<thead>
<tr>
<th>city</th>
<th>max</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hayward</td>
<td>37</td>
</tr>
</tbody>
</table>
```

which gives us the same results for only the cities that have all `temp_lo` values below 40. Finally, if we only care about cities whose names begin with “S”, we might do:

```sql
SELECT city, max(temp_lo)
FROM weather
WHERE city LIKE 'S%'
GROUP BY city
HAVING max(temp_lo) < 40;
```

The `LIKE` operator does pattern matching and is explained in Section 9.7.

It is important to understand the interaction between aggregates and SQL’s `WHERE` and `HAVING` clauses. The fundamental difference between `WHERE` and `HAVING` is this: `WHERE` selects input rows before groups and aggregates are computed (thus, it controls which rows go into the aggregate computation), whereas `HAVING` selects group rows after groups and aggregates are computed. Thus, the `WHERE` clause must not contain aggregate functions; it makes no sense to try to use an aggregate to determine which rows will
be inputs to the aggregates. On the other hand, the `HAVING` clause always contains aggregate functions. (Strictly speaking, you are allowed to write a `HAVING` clause that doesn't use aggregates, but it's seldom useful. The same condition could be used more efficiently at the `WHERE` stage.)

In the previous example, we can apply the city name restriction in `WHERE`, since it needs no aggregate. This is more efficient than adding the restriction to `HAVING`, because we avoid doing the grouping and aggregate calculations for all rows that fail the `WHERE` check.

### 2.8. Updates

You can update existing rows using the `UPDATE` command. Suppose you discover the temperature readings are all off by 2 degrees after November 28. You can correct the data as follows:

```
UPDATE weather
  SET temp_hi = temp_hi - 2, temp_lo = temp_lo - 2
WHERE date > '1994-11-28';
```

Look at the new state of the data:

```
SELECT * FROM weather;
```

```
+---------+-------+-------+-----+----------+
<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
<td>0.25</td>
<td>1994-11-27</td>
</tr>
<tr>
<td>San Francisco</td>
<td>41</td>
<td>55</td>
<td>0</td>
<td>1994-11-29</td>
</tr>
<tr>
<td>Hayward</td>
<td>35</td>
<td>52</td>
<td></td>
<td>1994-11-29</td>
</tr>
</tbody>
</table>
+---------+-------+-------+-----+----------+
```

(3 rows)

### 2.9. Deletions

Rows can be removed from a table using the `DELETE` command. Suppose you are no longer interested in the weather of Hayward. Then you can do the following to delete those rows from the table:

```
DELETE FROM weather WHERE city = 'Hayward';
```

All weather records belonging to Hayward are removed.

```
SELECT * FROM weather;
```

```
+---------+-------+-------+-----+----------+
<table>
<thead>
<tr>
<th>city</th>
<th>temp_lo</th>
<th>temp_hi</th>
<th>prcp</th>
<th>date</th>
</tr>
</thead>
<tbody>
<tr>
<td>San Francisco</td>
<td>46</td>
<td>50</td>
<td>0.25</td>
<td>1994-11-27</td>
</tr>
<tr>
<td>San Francisco</td>
<td>41</td>
<td>55</td>
<td>0</td>
<td>1994-11-29</td>
</tr>
</tbody>
</table>
+---------+-------+-------+-----+----------+
```

(2 rows)

One should be wary of statements of the form

```
DELETE FROM tablename;
```

Without a qualification, `DELETE` will remove all rows from the given table, leaving it empty. The system will not request confirmation before doing this!
Chapter 3. Advanced Features

3.1. Introduction

In the previous chapter we have covered the basics of using SQL to store and access your data in Postgres Pro. We will now discuss some more advanced features of SQL that simplify management and prevent loss or corruption of your data. Finally, we will look at some Postgres Pro extensions.

This chapter will on occasion refer to examples found in Chapter 2 to change or improve them, so it will be useful to have read that chapter. Some examples from this chapter can also be found in advanced.sql in the tutorial directory. This file also contains some sample data to load, which is not repeated here. (Refer to Section 2.1 for how to use the file.)

3.2. Views

Refer back to the queries in Section 2.6. Suppose the combined listing of weather records and city location is of particular interest to your application, but you do not want to type the query each time you need it. You can create a view over the query, which gives a name to the query that you can refer to like an ordinary table:

```sql
CREATE VIEW myview AS
    SELECT name, temp_lo, temp_hi, prcp, date, location
    FROM weather, cities
    WHERE city = name;
```

```sql
SELECT * FROM myview;
```

Making liberal use of views is a key aspect of good SQL database design. Views allow you to encapsulate the details of the structure of your tables, which might change as your application evolves, behind consistent interfaces.

Views can be used in almost any place a real table can be used. Building views upon other views is not uncommon.

3.3. Foreign Keys

Recall the weather and cities tables from Chapter 2. Consider the following problem: You want to make sure that no one can insert rows in the weather table that do not have a matching entry in the cities table. This is called maintaining the referential integrity of your data. In simplistic database systems this would be implemented (if at all) by first looking at the cities table to check if a matching record exists, and then inserting or rejecting the new weather records. This approach has a number of problems and is very inconvenient, so Postgres Pro can do this for you.

The new declaration of the tables would look like this:

```sql
CREATE TABLE cities (  
    name    varchar(80) primary key,  
    location point
);

CREATE TABLE weather (  
    city      varchar(80) references cities(name),  
    temp_lo   int,  
    temp_hi   int,  
    prcp      real,  
    date      date
);
```

Now try inserting an invalid record:
Advanced Features

INSERT INTO weather VALUES ('Berkeley', 45, 53, 0.0, '1994-11-28');
ERROR: insert or update on table "weather" violates foreign key constraint "weather_city_fkey"
DETAIL: Key (city)=(Berkeley) is not present in table "cities".

The behavior of foreign keys can be finely tuned to your application. We will not go beyond this simple example in this tutorial, but just refer you to Chapter 5 for more information. Making correct use of foreign keys will definitely improve the quality of your database applications, so you are strongly encouraged to learn about them.

3.4. Transactions

Transactions are a fundamental concept of all database systems. The essential point of a transaction is that it bundles multiple steps into a single, all-or-nothing operation. The intermediate states between the steps are not visible to other concurrent transactions, and if some failure occurs that prevents the transaction from completing, then none of the steps affect the database at all.

For example, consider a bank database that contains balances for various customer accounts, as well as total deposit balances for branches. Suppose that we want to record a payment of $100.00 from Alice's account to Bob's account. Simplifying outrageously, the SQL commands for this might look like:

```
UPDATE accounts SET balance = balance - 100.00
    WHERE name = 'Alice';
UPDATE branches SET balance = balance - 100.00
    WHERE name = (SELECT branch_name FROM accounts WHERE name = 'Alice');
UPDATE accounts SET balance = balance + 100.00
    WHERE name = 'Bob';
UPDATE branches SET balance = balance + 100.00
    WHERE name = (SELECT branch_name FROM accounts WHERE name = 'Bob');
```

The details of these commands are not important here; the important point is that there are several separate updates involved to accomplish this rather simple operation. Our bank's officers will want to be assured that either all these updates happen, or none of them happen. It would certainly not do for a system failure to result in Bob receiving $100.00 that was not debited from Alice. Nor would Alice long remain a happy customer if she was debited without Bob being credited. We need a guarantee that if something goes wrong partway through the operation, none of the steps executed so far will take effect. Grouping the updates into a transaction gives us this guarantee. A transaction is said to be atomic: from the point of view of other transactions, it either happens completely or not at all.

We also want a guarantee that once a transaction is completed and acknowledged by the database system, it has indeed been permanently recorded and won't be lost even if a crash ensues shortly thereafter. For example, if we are recording a cash withdrawal by Bob, we do not want any chance that the debit to his account will disappear in a crash just after he walks out the bank door. A transactional database guarantees that all the updates made by a transaction are logged in permanent storage (i.e., on disk) before the transaction is reported complete.

Another important property of transactional databases is closely related to the notion of atomic updates: when multiple transactions are running concurrently, each one should not be able to see the incomplete changes made by others. For example, if one transaction is busy totalling all the branch balances, it would not do for it to include the debit from Alice's branch but not the credit to Bob's branch, nor vice versa. So transactions must be all-or-nothing not only in terms of their permanent effect on the database, but also in terms of their visibility as they happen. The updates made so far by an open transaction are invisible to other transactions until the transaction completes, whereupon all the updates become visible simultaneously.

In Postgres Pro, a transaction is set up by surrounding the SQL commands of the transaction with BEGIN and COMMIT commands. So our banking transaction would actually look like:

```
BEGIN;
UPDATE accounts SET balance = balance - 100.00
```
WHERE name = 'Alice';
-- etc etc
COMMIT;

If, partway through the transaction, we decide we do not want to commit (perhaps we just noticed that Alice’s balance went negative), we can issue the command ROLLBACK instead of COMMIT, and all our updates so far will be canceled.

Postgres Pro actually treats every SQL statement as being executed within a transaction. If you do not issue a BEGIN command, then each individual statement has an implicit BEGIN and (if successful) COMMIT wrapped around it. A group of statements surrounded by BEGIN and COMMIT is sometimes called a transaction block.

**Note**

Some client libraries issue BEGIN and COMMIT commands automatically, so that you might get the effect of transaction blocks without asking. Check the documentation for the interface you are using.

It's possible to control the statements in a transaction in a more granular fashion through the use of savepoints. Savepoints allow you to selectively discard parts of the transaction, while committing the rest. After defining a savepoint with SAVEPOINT, you can if needed roll back to the savepoint with ROLLBACK TO. All the transaction's database changes between defining the savepoint and rolling back to it are discarded, but changes earlier than the savepoint are kept.

After rolling back to a savepoint, it continues to be defined, so you can roll back to it several times. Conversely, if you are sure you won't need to roll back to a particular savepoint again, it can be released, so the system can free some resources. Keep in mind that either releasing or rolling back to a savepoint will automatically release all savepoints that were defined after it.

All this is happening within the transaction block, so none of it is visible to other database sessions. When and if you commit the transaction block, the committed actions become visible as a unit to other sessions, while the rolled-back actions never become visible at all.

Remembering the bank database, suppose we debit $100.00 from Alice’s account, and credit Bob’s account, only to find later that we should have credited Wally’s account. We could do it using savepoints like this:

BEGIN;
UPDATE accounts SET balance = balance - 100.00
    WHERE name = 'Alice';
SAVEPOINT my_savepoint;
UPDATE accounts SET balance = balance + 100.00
    WHERE name = 'Bob';
-- oops ... forget that and use Wally's account
ROLLBACK TO my_savepoint;
UPDATE accounts SET balance = balance + 100.00
    WHERE name = 'Wally';
COMMIT;

This example is, of course, oversimplified, but there’s a lot of control possible in a transaction block through the use of savepoints. Moreover, ROLLBACK TO is the only way to regain control of a transaction block that was put in aborted state by the system due to an error, short of rolling it back completely and starting again.

### 3.5. Window Functions

A window function performs a calculation across a set of table rows that are somehow related to the current row. This is comparable to the type of calculation that can be done with an aggregate function.
However, window functions do not cause rows to become grouped into a single output row like non-window aggregate calls would. Instead, the rows retain their separate identities. Behind the scenes, the window function is able to access more than just the current row of the query result.

Here is an example that shows how to compare each employee’s salary with the average salary in his or her department:

```sql
SELECT depname, empno, salary, avg(salary) OVER (PARTITION BY depname) FROM empsalary;
```

<table>
<thead>
<tr>
<th>depname</th>
<th>empno</th>
<th>salary</th>
<th>avg</th>
</tr>
</thead>
<tbody>
<tr>
<td>develop</td>
<td>11</td>
<td>5200</td>
<td>5020.0000000000000000</td>
</tr>
<tr>
<td>develop</td>
<td>7</td>
<td>4200</td>
<td>5020.0000000000000000</td>
</tr>
<tr>
<td>develop</td>
<td>9</td>
<td>4500</td>
<td>5020.0000000000000000</td>
</tr>
<tr>
<td>develop</td>
<td>8</td>
<td>6000</td>
<td>5020.0000000000000000</td>
</tr>
<tr>
<td>develop</td>
<td>10</td>
<td>5200</td>
<td>5020.0000000000000000</td>
</tr>
<tr>
<td>personnel</td>
<td>5</td>
<td>3500</td>
<td>3700.0000000000000000</td>
</tr>
<tr>
<td>personnel</td>
<td>2</td>
<td>3900</td>
<td>3700.0000000000000000</td>
</tr>
<tr>
<td>sales</td>
<td>3</td>
<td>4800</td>
<td>4866.6666666666666667</td>
</tr>
<tr>
<td>sales</td>
<td>1</td>
<td>5000</td>
<td>4866.6666666666666667</td>
</tr>
<tr>
<td>sales</td>
<td>4</td>
<td>4800</td>
<td>4866.6666666666666667</td>
</tr>
</tbody>
</table>

(10 rows)

The first three output columns come directly from the table `empsalary`, and there is one output row for each row in the table. The fourth column represents an average taken across all the table rows that have the same `depname` value as the current row. (This actually is the same function as the non-window `avg` aggregate, but the `OVER` clause causes it to be treated as a window function and computed across the window frame.)

A window function call always contains an `OVER` clause directly following the window function’s name and argument(s). This is what syntactically distinguishes it from a normal function or non-window aggregate. The `OVER` clause determines exactly how the rows of the query are split up for processing by the window function. The `PARTITION BY` clause within `OVER` divides the rows into groups, or partitions, that share the same values of the `PARTITION BY` expression(s). For each row, the window function is computed across the rows that fall into the same partition as the current row.

You can also control the order in which rows are processed by window functions using `ORDER BY` within `OVER`. (The window `ORDER BY` does not even have to match the order in which the rows are output.) Here is an example:

```sql
SELECT depname, empno, salary,
    rank() OVER (PARTITION BY depname ORDER BY salary DESC)
FROM empsalary;
```

<table>
<thead>
<tr>
<th>depname</th>
<th>empno</th>
<th>salary</th>
<th>rank</th>
</tr>
</thead>
<tbody>
<tr>
<td>develop</td>
<td>8</td>
<td>6000</td>
<td>1</td>
</tr>
<tr>
<td>develop</td>
<td>10</td>
<td>5200</td>
<td>2</td>
</tr>
<tr>
<td>develop</td>
<td>11</td>
<td>5200</td>
<td>2</td>
</tr>
<tr>
<td>develop</td>
<td>9</td>
<td>4500</td>
<td>4</td>
</tr>
<tr>
<td>develop</td>
<td>7</td>
<td>4200</td>
<td>5</td>
</tr>
<tr>
<td>personnel</td>
<td>2</td>
<td>3900</td>
<td>1</td>
</tr>
<tr>
<td>personnel</td>
<td>5</td>
<td>3500</td>
<td>2</td>
</tr>
<tr>
<td>sales</td>
<td>1</td>
<td>5000</td>
<td>1</td>
</tr>
<tr>
<td>sales</td>
<td>4</td>
<td>4800</td>
<td>2</td>
</tr>
<tr>
<td>sales</td>
<td>3</td>
<td>4800</td>
<td>2</td>
</tr>
</tbody>
</table>

(10 rows)

As shown here, the `rank` function produces a numerical rank for each distinct `ORDER BY` value in the current row’s partition, using the order defined by the `ORDER BY` clause. `rank` needs no explicit parameter, because its behavior is entirely determined by the `OVER` clause.
The rows considered by a window function are those of the “virtual table” produced by the query's FROM clause as filtered by its WHERE, GROUP BY, and HAVING clauses if any. For example, a row removed because it does not meet the WHERE condition is not seen by any window function. A query can contain multiple window functions that slice up the data in different ways using different OVER clauses, but they all act on the same collection of rows defined by this virtual table.

We already saw that ORDER BY can be omitted if the ordering of rows is not important. It is also possible to omit PARTITION BY, in which case there is a single partition containing all rows.

There is another important concept associated with window functions: for each row, there is a set of rows within its partition called its window frame. Some window functions act only on the rows of the window frame, rather than of the whole partition. By default, if ORDER BY is supplied then the frame consists of all rows from the start of the partition up through the current row, plus any following rows that are equal to the current row according to the ORDER BY clause. When ORDER BY is omitted the default frame consists of all rows in the partition.  

Here is an example using sum:

```
SELECT salary, sum(salary) OVER () FROM empsalary;
```

```
salary |  sum
--------+-------
 5200   | 47100
 5000   | 47100
 3500   | 47100
 4800   | 47100
 3900   | 47100
 4200   | 47100
 4500   | 47100
 4800   | 47100
 6000   | 47100
 5200   | 47100
(10 rows)
```

Above, since there is no ORDER BY in the OVER clause, the window frame is the same as the partition, which for lack of PARTITION BY is the whole table; in other words each sum is taken over the whole table and so we get the same result for each output row. But if we add an ORDER BY clause, we get very different results:

```
SELECT salary, sum(salary) OVER (ORDER BY salary) FROM empsalary;
```

```
salary |  sum
--------+-------
 3500   |  3500
 3900   |  7400
 4200   | 11600
 4500   | 16100
 4800   | 25700
 4800   | 25700
 5000   | 30700
 5200   | 41100
 5200   | 41100
 6000   | 47100
(10 rows)
```

Here the sum is taken from the first (lowest) salary up through the current one, including any duplicates of the current one (notice the results for the duplicated salaries).

Window functions are permitted only in the SELECT list and the ORDER BY clause of the query. They are forbidden elsewhere, such as in GROUP BY, HAVING and WHERE clauses. This is because they logically execute after the processing of those clauses. Also, window functions execute after non-window

---

1 There are options to define the window frame in other ways, but this tutorial does not cover them. See Section 4.2.8 for details.
aggregate functions. This means it is valid to include an aggregate function call in the arguments of a window function, but not vice versa.

If there is a need to filter or group rows after the window calculations are performed, you can use a sub-select. For example:

```
SELECT depname, empno, salary, enroll_date
FROM
  (SELECT depname, empno, salary, enroll_date,
    rank() OVER (PARTITION BY depname ORDER BY salary DESC, empno) AS pos
     FROM empsalary
  ) AS ss
WHERE pos < 3;
```

The above query only shows the rows from the inner query having rank less than 3.

When a query involves multiple window functions, it is possible to write out each one with a separate `OVER` clause, but this is duplicative and error-prone if the same windowing behavior is wanted for several functions. Instead, each windowing behavior can be named in a `WINDOW` clause and then referenced in `OVER`. For example:

```
SELECT sum(salary) OVER w, avg(salary) OVER w
FROM empsalary
WINDOW w AS (PARTITION BY depname ORDER BY salary DESC);
```

More details about window functions can be found in Section 4.2.8, Section 9.22, Section 7.2.5, and the SELECT reference page.

### 3.6. Inheritance

Inheritance is a concept from object-oriented databases. It opens up interesting new possibilities of database design.

Let's create two tables: A table `cities` and a table `capitals`. Naturally, capitals are also cities, so you want some way to show the capitals implicitly when you list all cities. If you're really clever you might invent some scheme like this:

```
CREATE TABLE capitals (  
    name       text,  
    population real,  
    elevation  int,    -- (in ft)  
    state      char(2)  
) ;

CREATE TABLE non_capitals (  
    name       text,  
    population real,  
    elevation  int     -- (in ft)  
) ;

CREATE VIEW cities AS  
  SELECT name, population, elevation FROM capitals  
  UNION  
  SELECT name, population, elevation FROM non_capitals;
```

This works OK as far as querying goes, but it gets ugly when you need to update several rows, for one thing.

A better solution is this:

```
CREATE TABLE cities (  
    name       text,  
    population real,  
    elevation  int,    -- (in ft)  
    state      char(2)  
) ;
```
population real,
elevation int     -- (in ft)
);

CREATE TABLE capitals (  
  state     char(2) UNIQUE NOT NULL
) INHERITS (cities);

In this case, a row of capitals inherits all columns (name, population, and elevation) from its parent, cities. The type of the column name is text, a native Postgres Pro type for variable length character strings. The capitals table has an additional column, state, which shows its state abbreviation. In Postgres Pro, a table can inherit from zero or more other tables.

For example, the following query finds the names of all cities, including state capitals, that are located at an elevation over 500 feet:

```
SELECT name, elevation  
FROM cities  
WHERE elevation > 500;
```

which returns:

```
<table>
<thead>
<tr>
<th>name</th>
<th>elevation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Las Vegas</td>
<td>2174</td>
</tr>
<tr>
<td>Mariposa</td>
<td>1953</td>
</tr>
<tr>
<td>Madison</td>
<td>845</td>
</tr>
</tbody>
</table>
(3 rows)
```

On the other hand, the following query finds all the cities that are not state capitals and are situated at an elevation over 500 feet:

```
SELECT name, elevation  
FROM ONLY cities  
WHERE elevation > 500;
```

which returns:

```
<table>
<thead>
<tr>
<th>name</th>
<th>elevation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Las Vegas</td>
<td>2174</td>
</tr>
<tr>
<td>Mariposa</td>
<td>1953</td>
</tr>
</tbody>
</table>
(2 rows)
```

Here the ONLY before cities indicates that the query should be run over only the cities table, and not tables below cities in the inheritance hierarchy. Many of the commands that we have already discussed — SELECT, UPDATE, and DELETE — support this ONLY notation.

Note

Although inheritance is frequently useful, it has not been integrated with unique constraints or foreign keys, which limits its usefulness. See Section 5.10 for more detail.

3.7. Conclusion

Postgres Pro has many features not touched upon in this tutorial introduction, which has been oriented toward newer users of SQL. These features are discussed in more detail in the remainder of this book.

If you feel you need more introductory material, please visit the PostgreSQL web site for links to more resources.
Part II. The SQL Language

This part describes the use of the SQL language in Postgres Pro. We start with describing the general syntax of SQL, then explain how to create the structures to hold data, how to populate the database, and how to query it. The middle part lists the available data types and functions for use in SQL commands. The rest treats several aspects that are important for tuning a database for optimal performance.

The information in this part is arranged so that a novice user can follow it start to end to gain a full understanding of the topics without having to refer forward too many times. The chapters are intended to be self-contained, so that advanced users can read the chapters individually as they choose. The information in this part is presented in a narrative fashion in topical units. Readers looking for a complete description of a particular command should see Part VI.

Readers of this part should know how to connect to a Postgres Pro database and issue SQL commands. Readers that are unfamiliar with these issues are encouraged to read Part I first. SQL commands are typically entered using the Postgres Pro interactive terminal psql, but other programs that have similar functionality can be used as well.
Chapter 4. SQL Syntax

This chapter describes the syntax of SQL. It forms the foundation for understanding the following chapters which will go into detail about how SQL commands are applied to define and modify data.

We also advise users who are already familiar with SQL to read this chapter carefully because it contains several rules and concepts that are implemented inconsistently among SQL databases or that are specific to Postgres Pro.

4.1. Lexical Structure

SQL input consists of a sequence of commands. A command is composed of a sequence of tokens, terminated by a semicolon (";"). The end of the input stream also terminates a command. Which tokens are valid depends on the syntax of the particular command.

A token can be a key word, an identifier, a quoted identifier, a literal (or constant), or a special character symbol. Tokens are normally separated by whitespace (space, tab, newline), but need not be if there is no ambiguity (which is generally only the case if a special character is adjacent to some other token type).

For example, the following is (syntactically) valid SQL input:

```
SELECT * FROM MY_TABLE;
UPDATE MY_TABLE SET A = 5;
INSERT INTO MY_TABLE VALUES (3, 'hi there');
```

This is a sequence of three commands, one per line (although this is not required; more than one command can be on a line, and commands can usefully be split across lines).

Additionally, comments can occur in SQL input. They are not tokens, they are effectively equivalent to whitespace.

The SQL syntax is not very consistent regarding what tokens identify commands and which are operands or parameters. The first few tokens are generally the command name, so in the above example we would usually speak of a “SELECT”, an “UPDATE”, and an “INSERT” command. But for instance the UPDATE command always requires a SET token to appear in a certain position, and this particular variation of INSERT also requires a VALUES in order to be complete. The precise syntax rules for each command are described in Part VI.

4.1.1. Identifiers and Key Words

Tokens such as SELECT, UPDATE, or VALUES in the example above are examples of key words, that is, words that have a fixed meaning in the SQL language. The tokens MY_TABLE and A are examples of identifiers. They identify names of tables, columns, or other database objects, depending on the command they are used in. Therefore they are sometimes simply called “names”. Key words and identifiers have the same lexical structure, meaning that one cannot know whether a token is an identifier or a key word without knowing the language. A complete list of key words can be found in Appendix C.

SQL identifiers and key words must begin with a letter (a-z, but also letters with diacritical marks and non-Latin letters) or an underscore (_). Subsequent characters in an identifier or key word can be letters, underscores, digits (0-9), or dollar signs ($). Note that dollar signs are not allowed in identifiers according to the letter of the SQL standard, so their use might render applications less portable. The SQL standard will not define a key word that contains digits or starts or ends with an underscore, so identifiers of this form are safe against possible conflict with future extensions of the standard.

The system uses no more than NAMEDATALEN-1 bytes of an identifier; longer names can be written in commands, but they will be truncated. By default, NAMEDATALEN is 64 so the maximum identifier length is 63 bytes.

Key words and unquoted identifiers are case insensitive. Therefore:

```
UPDATE MY_TABLE SET A = 5;
```
can equivalently be written as:

```
UPDATE my_Table SET a = 5;
```

A convention often used is to write key words in upper case and names in lower case, e.g.:

```
UPDATE my_table SET a = 5;
```

There is a second kind of identifier: the delimited identifier or quoted identifier. It is formed by enclosing an arbitrary sequence of characters in double-quotes ("`). A delimited identifier is always an identifier, never a key word. So "select" could be used to refer to a column or table named "select", whereas an unquoted select would be taken as a key word and would therefore provoke a parse error when used where a table or column name is expected. The example can be written with quoted identifiers like this:

```
UPDATE "my_table" SET "a" = 5;
```

Quoted identifiers can contain any character, except the character with code zero. (To include a double quote, write two double quotes.) This allows constructing table or column names that would otherwise not be possible, such as ones containing spaces or ampersands. The length limitation still applies.

Quoting an identifier also makes it case-sensitive, whereas unquoted names are always folded to lower case. For example, the identifiers FOO, foo, and "foo" are considered the same by Postgres Pro, but "Foo" and "FOO" are different from these three and each other. (The folding of unquoted names to lower case in Postgres Pro is incompatible with the SQL standard, which says that unquoted names should be folded to upper case. Thus, foo should be equivalent to "FOO" not "foo" according to the standard. If you want to write portable applications you are advised to always quote a particular name or never quote it.)

A variant of quoted identifiers allows including escaped Unicode characters identified by their code points. This variant starts with Us (upper or lower case U followed by ampersand) immediately before the opening double quote, without any spaces in between, for example Us"foo". (Note that this creates an ambiguity with the operator &. Use spaces around the operator to avoid this problem.) Inside the quotes, Unicode characters can be specified in escaped form by writing a backslash followed by the four-digit hexadecimal code point number or alternatively a backslash followed by a plus sign followed by a six-digit hexadecimal code point number. For example, the identifier "data" could be written as Us\0061t\000061

The following less trivial example writes the Russian word “slon” (elephant) in Cyrillic letters:

```
Us\0441\043B\043E\043D
```

If a different escape character than backslash is desired, it can be specified using the UESCAPE clause after the string, for example:

```
Us\d!0061t!+000061" UESCAPE '!'
```

The escape character can be any single character other than a hexadecimal digit, the plus sign, a single quote, a double quote, or a whitespace character. Note that the escape character is written in single quotes, not double quotes, after UESCAPE.

To include the escape character in the identifier literally, write it twice.

Either the 4-digit or the 6-digit escape form can be used to specify UTF-16 surrogate pairs to compose characters with code points larger than U+FFFF, although the availability of the 6-digit form technically makes this unnecessary. (Surrogate pairs are not stored directly, but are combined into a single code point.)

If the server encoding is not UTF-8, the Unicode code point identified by one of these escape sequences is converted to the actual server encoding; an error is reported if that’s not possible.

### 4.1.2. Constants

There are three kinds of implicitly-typed constants in Postgres Pro: strings, bit strings, and numbers. Constants can also be specified with explicit types, which can enable more accurate representation and more efficient handling by the system. These alternatives are discussed in the following subsections.
4.1.2.1. String Constants

A string constant in SQL is an arbitrary sequence of characters bounded by single quotes (‘), for example 'This is a string'. To include a single-quote character within a string constant, write two adjacent single quotes, e.g., 'Dianne''s horse'. Note that this is not the same as a double-quote character (").

Two string constants that are only separated by whitespace with at least one newline are concatenated and effectively treated as if the string had been written as one constant. For example:

```
SELECT 'foo'
 'bar';
```

is equivalent to:

```
SELECT 'foobar';
```

but:

```
SELECT 'foo'      'bar';
```

is not valid syntax. (This slightly bizarre behavior is specified by SQL; Postgres Pro is following the standard.)

4.1.2.2. String Constants with C-Style Escapes

Postgres Pro also accepts “escape” string constants, which are an extension to the SQL standard. An escape string constant is specified by writing the letter E (upper or lower case) just before the opening single quote, e.g., E'foo'. (When continuing an escape string constant across lines, write E only before the first opening quote.) Within an escape string, a backslash character (\) begins a C-like backslash escape sequence, in which the combination of backslash and following character(s) represent a special byte value, as shown in Table 4.1.

**Table 4.1. Backslash Escape Sequences**

<table>
<thead>
<tr>
<th>Backslash Escape Sequence</th>
<th>Interpretation</th>
</tr>
</thead>
<tbody>
<tr>
<td>\b</td>
<td>backspace</td>
</tr>
<tr>
<td>\f</td>
<td>form feed</td>
</tr>
<tr>
<td>\n</td>
<td>newline</td>
</tr>
<tr>
<td>\r</td>
<td>carriage return</td>
</tr>
<tr>
<td>\t</td>
<td>tab</td>
</tr>
<tr>
<td>\o, \oo, \ooo (o = 0–7)</td>
<td>octal byte value</td>
</tr>
<tr>
<td>\xh, \xhh (h = 0–9, A–F)</td>
<td>hexadecimal byte value</td>
</tr>
<tr>
<td>\uxxxx, \Uxxxxxxxx (x = 0–9, A–F)</td>
<td>16 or 32-bit hexadecimal Unicode character value</td>
</tr>
</tbody>
</table>

Any other character following a backslash is taken literally. Thus, to include a backslash character, write two backslashes (\). Also, a single quote can be included in an escape string by writing \\, in addition to the normal way of ‘’.

It is your responsibility that the byte sequences you create, especially when using the octal or hexadecimal escapes, compose valid characters in the server character set encoding. A useful alternative is to use Unicode escapes or the alternative Unicode escape syntax, explained in Section 4.1.2.3; then the server will check that the character conversion is possible.

---

**Caution**

If the configuration parameter standard_conforming_strings is off, then Postgres Pro recognizes backslash escapes in both regular and escape string constants. However, as of PostgreSQL 9.1, the default is on, meaning that backslash escapes are recognized only in escape string constants. This
The character with the code zero cannot be in a string constant.

4.1.2.3. String Constants with Unicode Escapes

Postgres Pro also supports another type of escape syntax for strings that allows specifying arbitrary Unicode characters by code point. A Unicode escape string constant starts with $U\&$ (upper or lower case letter U followed by ampersand) immediately before the opening quote, without any spaces in between, for example $U\&'f\text{oo}'$. (Note that this creates an ambiguity with the operator $&$. Use spaces around the operator to avoid this problem.) Inside the quotes, Unicode characters can be specified in escaped form by writing a backslash followed by the four-digit hexadecimal code point number or alternatively a backslash followed by a plus sign followed by a six-digit hexadecimal code point number. For example, the string 'data' could be written as

$U\&'d\\0061t\+000061'$

The following less trivial example writes the Russian word “slon” (elephant) in Cyrillic letters:

$U\&'\0441\043B\043E\043D'$

If a different escape character than backslash is desired, it can be specified using the UESCAPE clause after the string, for example:

$U\&'d\0061t\+000061'$ UESCAPE '!' 

The escape character can be any single character other than a hexadecimal digit, the plus sign, a single quote, a double quote, or a whitespace character.

To include the escape character in the string literally, write it twice.

Either the 4-digit or the 6-digit escape form can be used to specify UTF-16 surrogate pairs to compose characters with code points larger than U+FFFF, although the availability of the 6-digit form technically makes this unnecessary. (Surrogate pairs are not stored directly, but are combined into a single code point.)

If the server encoding is not UTF-8, the Unicode code point identified by one of these escape sequences is converted to the actual server encoding; an error is reported if that's not possible.

Also, the Unicode escape syntax for string constants only works when the configuration parameter standard_conforming_strings is turned on. This is because otherwise this syntax could confuse clients that parse the SQL statements to the point that it could lead to SQL injections and similar security issues. If the parameter is set to off, this syntax will be rejected with an error message.

4.1.2.4. Dollar-Quoted String Constants

While the standard syntax for specifying string constants is usually convenient, it can be difficult to understand when the desired string contains many single quotes or backslashes, since each of those must be doubled. To allow more readable queries in such situations, Postgres Pro provides another way, called “dollar quoting”, to write string constants. A dollar-quoted string constant consists of a dollar sign ($\$), an optional “tag” of zero or more characters, another dollar sign, an arbitrary sequence of characters that makes up the string content, a dollar sign, the same tag that began this dollar quote, and a dollar sign. For example, here are two different ways to specify the string “Dianne's horse” using dollar quoting:

$$Dianne's~horse$$
Notice that inside the dollar-quoted string, single quotes can be used without needing to be escaped. Indeed, no characters inside a dollar-quoted string are ever escaped: the string content is always written literally. Backslashes are not special, and neither are dollar signs, unless they are part of a sequence matching the opening tag.

It is possible to nest dollar-quoted string constants by choosing different tags at each nesting level. This is most commonly used in writing function definitions. For example:

```sql
$function$
BEGIN
    RETURN ($1 - $q$[\t\r\n\v\\$q$];
END;
$function$
Here, the sequence $q$[\t\r\n\v\\$q$ represents a dollar-quoted literal string [\t\r\n\v\], which will be recognized when the function body is executed by Postgres Pro. But since the sequence does not match the outer dollar quoting delimiter $function$, it is just some more characters within the constant so far as the outer string is concerned.

The tag, if any, of a dollar-quoted string follows the same rules as an unquoted identifier, except that it cannot contain a dollar sign. Tags are case sensitive, so $tag$String content$tag$ is correct, but $TAG$String content$tag$ is not.

A dollar-quoted string that follows a keyword or identifier must be separated from it by whitespace; otherwise the dollar quoting delimiter would be taken as part of the preceding identifier.

Dollar quoting is not part of the SQL standard, but it is often a more convenient way to write complicated string literals than the standard-compliant single quote syntax. It is particularly useful when representing string constants inside other constants, as is often needed in procedural function definitions. With single-quote syntax, each backslash in the above example would have to be written as four backslashes, which would be reduced to two backslashes in parsing the original string constant, and then to one when the inner string constant is re-parsed during function execution.

### 4.1.2.5. Bit-String Constants

Bit-string constants look like regular string constants with a `B` (upper or lower case) immediately before the opening quote (no intervening whitespace), e.g., `B'1001'`. The only characters allowed within bit-string constants are `0` and `1`.

Alternatively, bit-string constants can be specified in hexadecimal notation, using a leading `X` (upper or lower case), e.g., `X'1FF'`. This notation is equivalent to a bit-string constant with four binary digits for each hexadecimal digit.

Both forms of bit-string constant can be continued across lines in the same way as regular string constants. Dollar quoting cannot be used in a bit-string constant.

### 4.1.2.6. Numeric Constants

Numeric constants are accepted in these general forms:

```sql
digits
digits.(digits)[e{+-}digits]
[digits].digits[e{+-}digits]
digitse{+-}digits
```

where `digits` is one or more decimal digits (0 through 9). At least one digit must be before or after the decimal point, if one is used. At least one digit must follow the exponent marker (e), if one is present. There cannot be any spaces or other characters embedded in the constant. Note that any leading plus or minus sign is not actually considered part of the constant; it is an operator applied to the constant.

These are some examples of valid numeric constants:
A numeric constant that contains neither a decimal point nor an exponent is initially presumed to be type \texttt{integer} if its value fits in type \texttt{integer} (32 bits); otherwise it is presumed to be type \texttt{bigint} if its value fits in type \texttt{bigint} (64 bits); otherwise it is taken to be type \texttt{numeric}. Constants that contain decimal points and/or exponents are always initially presumed to be type \texttt{numeric}.

The initially assigned data type of a numeric constant is just a starting point for the type resolution algorithms. In most cases the constant will be automatically coerced to the most appropriate type depending on context. When necessary, you can force a numeric value to be interpreted as a specific data type by casting it. For example, you can force a numeric value to be treated as type \texttt{real(float4)} by writing:

\begin{verbatim}
REAL '1.23' -- string style
1.23::REAL   -- Postgres Pro (historical) style
\end{verbatim}

These are actually just special cases of the general casting notations discussed next.

### 4.1.2.7. Constants of Other Types

A constant of an \textit{arbitrary} type can be entered using any one of the following notations:

\begin{verbatim}
type 'string'
'string'::type
CAST ( 'string' AS type )
\end{verbatim}

The string constant's text is passed to the input conversion routine for the type called \texttt{type}. The result is a constant of the indicated type. The explicit type cast can be omitted if there is no ambiguity as to the type the constant must be (for example, when it is assigned directly to a table column), in which case it is automatically coerced.

The string constant can be written using either regular SQL notation or dollar-quoting.

It is also possible to specify a type coercion using a function-like syntax:

\begin{verbatim}
typename ( 'string' )
\end{verbatim}

but not all type names can be used in this way; see Section 4.2.9 for details.

The ::, \texttt{CAST()}, and function-call syntaxes can also be used to specify run-time type conversions of arbitrary expressions, as discussed in Section 4.2.9. To avoid syntactic ambiguity, the \texttt{type 'string'} syntax can only be used to specify the type of a simple literal constant. Another restriction on the \texttt{type 'string'} syntax is that it does not work for array types; use :: or \texttt{CAST()} to specify the type of an array constant.

The \texttt{CAST()} syntax conforms to SQL. The \texttt{type 'string'} syntax is a generalization of the standard: SQL specifies this syntax only for a few data types, but Postgres Pro allows it for all types. The syntax with :: is historical Postgres Pro usage, as is the function-call syntax.

### 4.1.3. Operators

An operator name is a sequence of up to \texttt{NAMEDATALEN}-1 (63 by default) characters from the following list:

\begin{verbatim}
+ - * / < > = ! @ # % ^ & | ` ?
\end{verbatim}

There are a few restrictions on operator names, however:

- -- and /* cannot appear anywhere in an operator name, since they will be taken as the start of a comment.
• A multiple-character operator name cannot end in + or −, unless the name also contains at least one of these characters:

    ~ ! @ # % ^ & | ` ?

For example, @− is an allowed operator name, but *− is not. This restriction allows Postgres Pro to parse SQL-compliant queries without requiring spaces between tokens.

When working with non-SQL-standard operator names, you will usually need to separate adjacent operators with spaces to avoid ambiguity. For example, if you have defined a prefix operator named @, you cannot write X*@Y; you must write X* @Y to ensure that Postgres Pro reads it as two operator names not one.

4.1.4. Special Characters

Some characters that are not alphanumeric have a special meaning that is different from being an operator. Details on the usage can be found at the location where the respective syntax element is described. This section only exists to advise the existence and summarize the purposes of these characters.

• A dollar sign ($) followed by digits is used to represent a positional parameter in the body of a function definition or a prepared statement. In other contexts the dollar sign can be part of an identifier or a dollar-quoted string constant.

• Parentheses (()) have their usual meaning to group expressions and enforce precedence. In some cases parentheses are required as part of the fixed syntax of a particular SQL command.

• Brackets ([]) are used to select the elements of an array. See Section 8.15 for more information on arrays.

• Commas (,) are used in some syntactical constructs to separate the elements of a list.

• The semicolon (;) terminates an SQL command. It cannot appear anywhere within a command, except within a string constant or quoted identifier.

• The colon (:) is used to select “slices” from arrays. (See Section 8.15.) In certain SQL dialects (such as Embedded SQL), the colon is used to prefix variable names.

• The asterisk (*) is used in some contexts to denote all the fields of a table row or composite value. It also has a special meaning when used as the argument of an aggregate function, namely that the aggregate does not require any explicit parameter.

• The period (.) is used in numeric constants, and to separate schema, table, and column names.

4.1.5. Comments

A comment is a sequence of characters beginning with double dashes and extending to the end of the line, e.g.:

```sql
-- This is a standard SQL comment
```

Alternatively, C-style block comments can be used:

```sql
/* multiline comment
 * with nesting: /* nested block comment */
 */
```

where the comment begins with /* and extends to the matching occurrence of */. These block comments nest, as specified in the SQL standard but unlike C, so that one can comment out larger blocks of code that might contain existing block comments.

A comment is removed from the input stream before further syntax analysis and is effectively replaced by whitespace.

4.1.6. Operator Precedence
Table 4.2 shows the precedence and associativity of the operators in Postgres Pro. Most operators have the same precedence and are left-associative. The precedence and associativity of the operators is hard-wired into the parser. Add parentheses if you want an expression with multiple operators to be parsed in some other way than what the precedence rules imply.

### Table 4.2. Operator Precedence (highest to lowest)

<table>
<thead>
<tr>
<th>Operator/Element</th>
<th>Associativity</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>.</td>
<td>left</td>
<td>table/column name separator</td>
</tr>
<tr>
<td>::</td>
<td>left</td>
<td>Postgres Pro-style typecast</td>
</tr>
<tr>
<td>[ ]</td>
<td>left</td>
<td>array element selection</td>
</tr>
<tr>
<td>+ -</td>
<td>right</td>
<td>unary plus, unary minus</td>
</tr>
<tr>
<td>^</td>
<td>left</td>
<td>exponentiation</td>
</tr>
<tr>
<td>*/%</td>
<td>left</td>
<td>multiplication, division, modulo</td>
</tr>
<tr>
<td>(any other operator)</td>
<td>left</td>
<td>all other native and user-defined operators</td>
</tr>
<tr>
<td>BETWEEN IN LIKE ILIKE SIMILAR</td>
<td>left</td>
<td>range containment, set membership, string matching</td>
</tr>
<tr>
<td>&lt; &gt; = &lt;= &gt;= &lt;&gt;</td>
<td></td>
<td>comparison operators</td>
</tr>
<tr>
<td>IS ISNULL NOTNULL</td>
<td></td>
<td>IS TRUE, IS FALSE, IS NULL, IS DISTINCT FROM, etc</td>
</tr>
<tr>
<td>NOT</td>
<td>right</td>
<td>logical negation</td>
</tr>
<tr>
<td>AND</td>
<td>left</td>
<td>logical conjunction</td>
</tr>
<tr>
<td>OR</td>
<td>left</td>
<td>logical disjunction</td>
</tr>
</tbody>
</table>

Note that the operator precedence rules also apply to user-defined operators that have the same names as the built-in operators mentioned above. For example, if you define a “+” operator for some custom data type it will have the same precedence as the built-in “+” operator, no matter what yours does.

When a schema-qualified operator name is used in the OPERATOR syntax, as for example in:

```
SELECT 3 OPERATOR(pg_catalog.+) 4;
```

the OPERATOR construct is taken to have the default precedence shown in Table 4.2 for “any other operator”. This is true no matter which specific operator appears inside OPERATOR().

### PostgreSQL Version Before 9.5

PostgreSQL versions before 9.5 used slightly different operator precedence rules. In particular, `<>=` and `<>` used to be treated as generic operators; `IS` tests used to have higher priority; and `NOT BETWEEN` and related constructs acted inconsistently, being taken in some cases as having the precedence of `NOT` rather than `BETWEEN`. These rules were changed for better compliance with the SQL standard and to reduce confusion from inconsistent treatment of logically equivalent constructs. In most cases, these changes will result in no behavioral change, or perhaps in “no such operator” failures which can be resolved by adding parentheses. However there are corner cases in which a query might change behavior without any parsing error being reported.

### 4.2. Value Expressions

Value expressions are used in a variety of contexts, such as in the target list of the `SELECT` command, as new column values in `INSERT` or `UPDATE`, or in search conditions in a number of commands. The
result of a value expression is sometimes called a scalar, to distinguish it from the result of a table expression (which is a table). Value expressions are therefore also called scalar expressions (or even simply expressions). The expression syntax allows the calculation of values from primitive parts using arithmetic, logical, set, and other operations.

A value expression is one of the following:
- A constant or literal value
- A column reference
- A positional parameter reference, in the body of a function definition or prepared statement
- A subscripted expression
- A field selection expression
- An operator invocation
- A function call
- An aggregate expression
- A window function call
- A type cast
- A collation expression
- A scalar subquery
- An array constructor
- A row constructor
- Another value expression in parentheses (used to group subexpressions and override precedence)

In addition to this list, there are a number of constructs that can be classified as an expression but do not follow any general syntax rules. These generally have the semantics of a function or operator and are explained in the appropriate location in Chapter 9. An example is the IS NULL clause.

We have already discussed constants in Section 4.1.2. The following sections discuss the remaining options.

### 4.2.1. Column References

A column can be referenced in the form:

```
correlation.columnname
```

`correlation` is the name of a table (possibly qualified with a schema name), or an alias for a table defined by means of a FROM clause. The correlation name and separating dot can be omitted if the column name is unique across all the tables being used in the current query. (See also Chapter 7.)

### 4.2.2. Positional Parameters

A positional parameter reference is used to indicate a value that is supplied externally to an SQL statement. Parameters are used in SQL function definitions and in prepared queries. Some client libraries also support specifying data values separately from the SQL command string, in which case parameters are used to refer to the out-of-line data values. The form of a parameter reference is:

```
$number
```

For example, consider the definition of a function, `dept`, as:

```
CREATE FUNCTION dept(text) RETURNS dept
    AS $$ SELECT * FROM dept WHERE name = $1 $$
    LANGUAGE SQL;
```

Here the `$1` references the value of the first function argument whenever the function is invoked.
4.2.3. Subscripts

If an expression yields a value of an array type, then a specific element of the array value can be extracted by writing

expression[subscript]

or multiple adjacent elements (an “array slice”) can be extracted by writing

expression[lower_subscript:upper_subscript]

(Here, the brackets [ ] are meant to appear literally.) Each subscript is itself an expression, which will be rounded to the nearest integer value.

In general the array expression must be parenthesized, but the parentheses can be omitted when the expression to be subscripted is just a column reference or positional parameter. Also, multiple subscripts can be concatenated when the original array is multidimensional. For example:

mytable.arraycolumn[4]
mytable.two_d_column[17][34]
$1[10:42]
(arrayfunction(a,b))[42]

The parentheses in the last example are required. See Section 8.15 for more about arrays.

4.2.4. Field Selection

If an expression yields a value of a composite type (row type), then a specific field of the row can be extracted by writing

expression.fieldname

In general the row expression must be parenthesized, but the parentheses can be omitted when the expression to be selected from is just a table reference or positional parameter. For example:

mytable.mycolumn
$1.somecolumn
(rowfunction(a,b)).col3

(Thus, a qualified column reference is actually just a special case of the field selection syntax.) An important special case is extracting a field from a table column that is of a composite type:

(compositecol).somefield
(mytable.compositecol).somefield

The parentheses are required here to show that compositecol is a column name not a table name, or that mytable is a table name not a schema name in the second case.

You can ask for all fields of a composite value by writing .*:

(compositecol).*

This notation behaves differently depending on context; see Section 8.16.5 for details.

4.2.5. Operator Invocations

There are two possible syntaxes for an operator invocation:

expression operator expression (binary infix operator)
operator expression (unary prefix operator)

where the operator token follows the syntax rules of Section 4.1.3, or is one of the key words AND, OR, and NOT, or is a qualified operator name in the form:

OPERATOR(schema.operatorsname)

Which particular operators exist and whether they are unary or binary depends on what operators have been defined by the system or the user. Chapter 9 describes the built-in operators.
4.2.6. Function Calls

The syntax for a function call is the name of a function (possibly qualified with a schema name), followed by its argument list enclosed in parentheses:

function_name ( [expression [ , expression ... ] ] )

For example, the following computes the square root of 2:

sqrt(2)

The list of built-in functions is in Chapter 9. Other functions can be added by the user.

When issuing queries in a database where some users mistrust other users, observe security precautions from Section 10.3 when writing function calls.

The arguments can optionally have names attached. See Section 4.3 for details.

Note

A function that takes a single argument of composite type can optionally be called using field-selection syntax, and conversely field selection can be written in functional style. That is, the notations col(table) and table.col are interchangeable. This behavior is not SQL-standard but is provided in Postgres Pro because it allows use of functions to emulate “computed fields”. For more information see Section 8.16.5.

4.2.7. Aggregate Expressions

An aggregate expression represents the application of an aggregate function across the rows selected by a query. An aggregate function reduces multiple inputs to a single output value, such as the sum or average of the inputs. The syntax of an aggregate expression is one of the following:

aggregate_name ( expression [ , ... ] [ order_by_clause ] ) [ FILTER ( WHERE filter_clause ) ]
aggregate_name ( ALL expression [ , ... ] [ order_by_clause ] ) [ FILTER ( WHERE filter_clause ) ]
aggregate_name ( DISTINCT expression [ , ... ] [ order_by_clause ] ) [ FILTER ( WHERE filter_clause ) ]
aggregate_name ( * ) [ FILTER ( WHERE filter_clause ) ]
aggregate_name ( [ expression [ , ... ] ] ) WITHIN GROUP ( order_by_clause ) [ FILTER ( WHERE filter_clause ) ]

where aggregate_name is a previously defined aggregate (possibly qualified with a schema name) and expression is any value expression that does not itself contain an aggregate expression or a window function call. The optional order_by_clause and filter_clause are described below.

The first form of aggregate expression invokes the aggregate once for each input row. The second form is the same as the first, since ALL is the default. The third form invokes the aggregate once for each distinct value of the expression (or distinct set of values, for multiple expressions) found in the input rows. The fourth form invokes the aggregate once for each input row; since no particular input value is specified, it is generally only useful for the count(*) aggregate function. The last form is used with ordered-set aggregate functions, which are described below.

Most aggregate functions ignore null inputs, so that rows in which one or more of the expression(s) yield null are discarded. This can be assumed to be true, unless otherwise specified, for all built-in aggregates.

For example, count(*) yields the total number of input rows; count(f1) yields the number of input rows in which f1 is non-null, since count ignores nulls; and count(distinct f1) yields the number of distinct non-null values of f1.
Ordinarily, the input rows are fed to the aggregate function in an unspecified order. In many cases this does not matter; for example, \( \text{min} \) produces the same result no matter what order it receives the inputs in. However, some aggregate functions (such as \( \text{array_agg} \) and \( \text{string_agg} \)) produce results that depend on the ordering of the input rows. When using such an aggregate, the optional \texttt{order_by_clause} can be used to specify the desired ordering. The \texttt{order_by_clause} has the same syntax as for a query-level \texttt{ORDER BY} clause, as described in Section 7.5, except that its expressions are always just expressions and cannot be output-column names or numbers. For example:

\[
\text{SELECT array_agg(a ORDER BY b DESC) FROM table;}
\]

When dealing with multiple-argument aggregate functions, note that the \texttt{ORDER BY} clause goes after all the aggregate arguments. For example, write this:

\[
\text{SELECT string_agg(a, ',') ORDER BY a) FROM table;}
\]

not this:

\[
\text{SELECT string_agg(a ORDER BY a, ',') FROM table; -- incorrect}
\]

The latter is syntactically valid, but it represents a call of a single-argument aggregate function with two \texttt{ORDER BY} keys (the second one being rather useless since it's a constant).

If \texttt{DISTINCT} is specified in addition to an \texttt{order_by_clause}, then all the \texttt{ORDER BY} expressions must match regular arguments of the aggregate; that is, you cannot sort on an expression that is not included in the \texttt{DISTINCT} list.

Placing \texttt{ORDER BY} within the aggregate's regular argument list, as described so far, is used when ordering the input rows for general-purpose and statistical aggregates, for which ordering is optional. There is a subclass of aggregate functions called \texttt{ordered-set aggregates} for which an \texttt{order_by_clause} is required, usually because the aggregate's computation is only sensible in terms of a specific ordering of its input rows. Typical examples of ordered-set aggregates include rank and percentile calculations. For an ordered-set aggregate, the \texttt{order_by_clause} is written inside \texttt{WITHIN GROUP (...)}, as shown in the final syntax alternative above. The expressions in the \texttt{order_by_clause} are evaluated once per input row just like regular aggregate arguments, sorted as per the \texttt{order_by_clause}'s requirements, and fed to the aggregate function as input arguments. (This is unlike the case for a non-\texttt{WITHIN GROUP} order_by_clause, which is not treated as argument(s) to the aggregate function.) The argument expressions preceding \texttt{WITHIN GROUP}, if any, are called \texttt{direct arguments} to distinguish them from the \texttt{aggregated arguments} listed in the \texttt{order_by_clause}. Unlike regular aggregate arguments, direct arguments are evaluated only once per aggregate call, not once per input row. This means that they can contain variables only if those variables are grouped by \texttt{GROUP BY}; this restriction is the same as if the direct arguments were not inside an aggregate expression at all. Direct arguments are typically used for things like percentile fractions, which only make sense as a single value per aggregation calculation. The direct argument list can be empty; in this case, write just () not (*). (Postgres Pro will actually accept either spelling, but only the first way conforms to the SQL standard.)

An example of an ordered-set aggregate call is:

\[
\begin{align*}
\text{SELECT percentile_cont(0.5) WITHIN GROUP (ORDER BY income) FROM households;} \\
\text{percentile_cont} \\
\end{align*}
\]

\[
\begin{align*}
\text{------------------} \\
50489
\end{align*}
\]

which obtains the 50th percentile, or median, value of the \texttt{income} column from table \texttt{households}. Here, \(0.5\) is a direct argument; it would make no sense for the percentile fraction to be a value varying across rows.
If `FILTER` is specified, then only the input rows for which the `filter_clause` evaluates to true are fed to the aggregate function; other rows are discarded. For example:

```
SELECT
  count(*) AS unfiltered,
  count(*) FILTER (WHERE i < 5) AS filtered
FROM generate_series(1,10) AS s(i);
```

```
<table>
<thead>
<tr>
<th>unfiltered</th>
<th>filtered</th>
</tr>
</thead>
<tbody>
<tr>
<td>10</td>
<td>4</td>
</tr>
</tbody>
</table>
```

The predefined aggregate functions are described in Section 9.21. Other aggregate functions can be added by the user.

An aggregate expression can only appear in the result list or `HAVING` clause of a `SELECT` command. It is forbidden in other clauses, such as `WHERE`, because those clauses are logically evaluated before the results of aggregates are formed.

When an aggregate expression appears in a subquery (see Section 4.2.11 and Section 9.23), the aggregate is normally evaluated over the rows of the subquery. But an exception occurs if the aggregate’s arguments (and `filter_effects` if any) contain only outer-level variables: the aggregate then belongs to the nearest such outer level, and is evaluated over the rows of that query. The aggregate expression as a whole is then an outer reference for the subquery it appears in, and acts as a constant over any one evaluation of that subquery. The restriction about appearing only in the result list or `HAVING` clause applies with respect to the query level that the aggregate belongs to.

### 4.2.8. Window Function Calls

A *window function call* represents the application of an aggregate-like function over some portion of the rows selected by a query. Unlike non-window aggregate calls, this is not tied to grouping of the selected rows into a single output row — each row remains separate in the query output. However the window function has access to all the rows that would be part of the current row’s group according to the grouping specification (PARTITION BY list) of the window function call. The syntax of a window function call is one of the following:

```
function_name ([expression [, expression ... ]]) [ FILTER ( WHERE filter_clause ) ]
OVER window_name
```

```
function_name ([expression [, expression ... ]]) [ FILTER ( WHERE filter_clause ) ]
OVER ( window_definition )
```

```
function_name ( * ) [ FILTER ( WHERE filter_clause ) ] OVER window_name
```

```
function_name ( * ) [ FILTER ( WHERE filter_clause ) ] OVER ( window_definition )
```

where `window_definition` has the syntax

```
[ existing_window_name ]
[ PARTITION BY expression [, ... ] ]
[ ORDER BY expression [ ASC | DESC | USING operator ] [ NULLS { FIRST | LAST } ] [ , ... ] ]
[ frame_clause ]
```

The optional `frame_clause` can be one of

```
{ RANGE | ROWS | GROUPS } frame_start [ frame_exclusion ]
{ RANGE | ROWS | GROUPS } BETWEEN frame_start AND frame_end [ frame_exclusion ]
```

where `frame_start` and `frame_end` can be one of

UNBOUNDED PRECEDING
offset PRECEDING
CURRENT ROW
offset FOLLOWING
UNBOUNDED FOLLOWING

and frame_exclusion can be one of

EXCLUDE CURRENT ROW
EXCLUDE GROUP
EXCLUDE TIES
EXCLUDE NO OTHERS

Here, expression represents any value expression that does not itself contain window function calls.

window_name is a reference to a named window specification defined in the query’s WINDOW clause. Alternatively, a full window_definition can be given within parentheses, using the same syntax as for defining a named window in the WINDOW clause; see the SELECT reference page for details. It’s worth pointing out that OVER wname is not exactly equivalent to OVER (wname ...); the latter implies copying and modifying the window definition, and will be rejected if the referenced window specification includes a frame clause.

The PARTITION BY clause groups the rows of the query into partitions, which are processed separately by the window function. PARTITION BY works similarly to a query-level GROUP BY clause, except that its expressions are always just expressions and cannot be output-column names or numbers. Without PARTITION BY, all rows produced by the query are treated as a single partition. The ORDER BY clause determines the order in which the rows of a partition are processed by the window function. It works similarly to a query-level ORDER BY clause, but likewise cannot use output-column names or numbers. Without ORDER BY, rows are processed in an unspecified order.

The frame_clause specifies the set of rows constituting the window frame, which is a subset of the current partition, for those window functions that act on the frame instead of the whole partition. The set of rows in the frame can vary depending on which row is the current row. The frame can be specified in RANGE, ROWS or GROUPS mode; in each case, it runs from the frame_start to the frame_end. If frame_end is omitted, the end defaults to CURRENT ROW.

A frame_start of UNBOUNDED PRECEDING means that the frame starts with the first row of the partition, and similarly a frame_end of UNBOUNDED FOLLOWING means that the frame ends with the last row of the partition.

In RANGE or GROUPS mode, a frame_start of CURRENT ROW means the frame starts with the current row’s first peer row (a row that the window’s ORDER BY clause sorts as equivalent to the current row), while a frame_end of CURRENT ROW means the frame ends with the current row’s last peer row. In ROWS mode, CURRENT ROW simply means the current row.

In the offset PRECEDING and offset FOLLOWING frame options, the offset must be an expression not containing any variables, aggregate functions, or window functions. The meaning of the offset depends on the frame mode:

• In ROWS mode, the offset must yield a non-null, non-negative integer; and the option means that the frame starts or ends the specified number of rows before or after the current row.

• In GROUPS mode, the offset again must yield a non-null, non-negative integer; and the option means that the frame starts or ends the specified number of peer groups before or after the current row’s peer group, where a peer group is a set of rows that are equivalent in the ORDER BY ordering. (There must be an ORDER BY clause in the window definition to use GROUPS mode.)

• In RANGE mode, these options require that the ORDER BY clause specify exactly one column. The offset specifies the maximum difference between the value of that column in the current row and its value in preceding or following rows of the frame. The data type of the offset expression varies depending on the data type of the ordering column. For numeric ordering columns it is typically of the same type as the ordering column, but for datetime ordering columns it is an interval. For example, if the ordering column is of type date or timestamp, one could write RANGE BETWEEN '1 day' PRECEDING AND '10 days' FOLLOWING. The offset is still required to be non-null and non-negative, though the meaning of “non-negative” depends on its data type.
In any case, the distance to the end of the frame is limited by the distance to the end of the partition, so that for rows near the partition ends the frame might contain fewer rows than elsewhere.

Notice that in both ROWS and GROUPS mode, 0 PRECEDING and 0 FOLLOWING are equivalent to CURRENT ROW. This normally holds in RANGE mode as well, for an appropriate data-type-specific meaning of “zero”.

The frame_exclusion option allows rows around the current row to be excluded from the frame, even if they would be included according to the frame start and frame end options. EXCLUDE CURRENT ROW excludes the current row from the frame. EXCLUDE GROUP excludes the current row and its ordering peers from the frame. EXCLUDE TIES excludes any peers of the current row from the frame, but not the current row itself. EXCLUDE NO OTHERS simply specifies explicitly the default behavior of not excluding the current row or its peers.

The default framing option is RANGE UNBOUNDED PRECEDING, which is the same as RANGE BETWEEN UNBOUNDED PRECEDING AND CURRENT ROW. With ORDER BY, this sets the frame to be all rows from the partition start up through the current row’s last ORDER BY peer. Without ORDER BY, this means all rows of the partition are included in the window frame, since all rows become peers of the current row.

Restrictions are that frame_start cannot be UNBOUNDED FOLLOWING, frame_end cannot be UNBOUNDED PRECEDING, and the frame_end choice cannot appear earlier in the above list of frame_start and frame_end options than the frame_start choice does — for example RANGE BETWEEN CURRENT ROW AND offset PRECEDING is not allowed. But, for example, ROWS BETWEEN 7 PRECEDING AND 8 PRECEDING is allowed, even though it would never select any rows.

If FILTER is specified, then only the input rows for which the filter_clause evaluates to true are fed to the window function; other rows are discarded. Only window functions that are aggregates accept a FILTER clause.

The built-in window functions are described in Table 9.62. Other window functions can be added by the user. Also, any built-in or user-defined general-purpose or statistical aggregate can be used as a window function. (Ordered-set and hypothetical-set aggregates cannot presently be used as window functions.)

The syntaxes using * are used for calling parameter-less aggregate functions as window functions, for example count(*) OVER (PARTITION BY x ORDER BY y). The asterisk (*) is customarily not used for window-specific functions. Window-specific functions do not allow DISTINCT or ORDER BY to be used within the function argument list.

Window function calls are permitted only in the SELECT list and the ORDER BY clause of the query.

More information about window functions can be found in Section 3.5, Section 9.22, and Section 7.2.5.

4.2.9. Type Casts

A type cast specifies a conversion from one data type to another. Postgres Pro accepts two equivalent syntaxes for type casts:

```
CAST ( expression AS type )
expression::type
```

The CAST syntax conforms to SQL; the syntax with :: is historical Postgres Pro usage.

When a cast is applied to a value expression of a known type, it represents a run-time type conversion. The cast will succeed only if a suitable type conversion operation has been defined. Notice that this is subtly different from the use of casts with constants, as shown in Section 4.1.2.7. A cast applied to an unadorned string literal represents the initial assignment of a type to a literal constant value, and so it will succeed for any type (if the contents of the string literal are acceptable input syntax for the data type).

An explicit type cast can usually be omitted if there is no ambiguity as to the type that a value expression must produce (for example, when it is assigned to a table column); the system will automatically apply
a type cast in such cases. However, automatic casting is only done for casts that are marked “OK to apply implicitly” in the system catalogs. Other casts must be invoked with explicit casting syntax. This restriction is intended to prevent surprising conversions from being applied silently.

It is also possible to specify a type cast using a function-like syntax:

```sql
typename ( expression )
```

However, this only works for types whose names are also valid as function names. For example, `double precision` cannot be used this way, but the equivalent `float8` can. Also, the names `interval`, `time`, and `timestamp` can only be used in this fashion if they are double-quoted, because of syntactic conflicts. Therefore, the use of the function-like cast syntax leads to inconsistencies and should probably be avoided.

The function-like syntax is in fact just a function call. When one of the two standard cast syntaxes is used to do a run-time conversion, it will internally invoke a registered function to perform the conversion. By convention, these conversion functions have the same name as their output type, and thus the “function-like syntax” is nothing more than a direct invocation of the underlying conversion function. Obviously, this is not something that a portable application should rely on. For further details see `CREATE CAST`.

### 4.2.10. Collation Expressions

The `COLLATE` clause overrides the collation of an expression. It is appended to the expression it applies to:

```sql
expr COLLATE collation
```

where `collation` is a possibly schema-qualified identifier. The `COLLATE` clause binds tighter than operators; parentheses can be used when necessary.

If no collation is explicitly specified, the database system either derives a collation from the columns involved in the expression, or it defaults to the default collation of the database if no column is involved in the expression.

The two common uses of the `COLLATE` clause are overriding the sort order in an `ORDER BY` clause, for example:

```sql
SELECT a, b, c FROM tbl WHERE ... ORDER BY a COLLATE "C";
```

and overriding the collation of a function or operator call that has locale-sensitive results, for example:

```sql
SELECT * FROM tbl WHERE a > 'foo' COLLATE "C";
```

Note that in the latter case the `COLLATE` clause is attached to an input argument of the operator we wish to affect. It doesn't matter which argument of the operator or function call the `COLLATE` clause is attached to, because the collation that is applied by the operator or function is derived by considering all arguments, and an explicit `COLLATE` clause will override the collations of all other arguments. (Attaching non-matching `COLLATE` clauses to more than one argument, however, is an error. For more details see Section 22.2.) Thus, this gives the same result as the previous example:

```sql
SELECT * FROM tbl WHERE a COLLATE "C" > 'foo';
```

But this is an error:

```sql
SELECT * FROM tbl WHERE (a > 'foo') COLLATE "C";
```

because it attempts to apply a collation to the result of the `>` operator, which is of the non-collatable data type `boolean`.

### 4.2.11. Scalar Subqueries
A scalar subquery is an ordinary SELECT query in parentheses that returns exactly one row with one column. (See Chapter 7 for information about writing queries.) The SELECT query is executed and the single returned value is used in the surrounding value expression. It is an error to use a query that returns more than one row or more than one column as a scalar subquery. (But if, during a particular execution, the subquery returns no rows, there is no error; the scalar result is taken to be null.) The subquery can refer to variables from the surrounding query, which will act as constants during any one evaluation of the subquery. See also Section 9.23 for other expressions involving subqueries.

For example, the following finds the largest city population in each state:

```
SELECT name, (SELECT max(pop) FROM cities WHERE cities.state = states.name)
FROM states;
```

### 4.2.12. Array Constructors

An array constructor is an expression that builds an array value using values for its member elements. A simple array constructor consists of the key word ARRAY, a left square bracket [], a list of expressions (separated by commas) for the array element values, and finally a right square bracket ]. For example:

```
SELECT ARRAY[1,2,3+4];
```

```
array
-------
{1,2,7}
(1 row)
```

By default, the array element type is the common type of the member expressions, determined using the same rules as for UNION or CASE constructs (see Section 10.5). You can override this by explicitly casting the array constructor to the desired type, for example:

```
SELECT ARRAY[1,2,22.7]::integer[];
```

```
array
-------
{1,2,23}
(1 row)
```

This has the same effect as casting each expression to the array element type individually. For more on casting, see Section 4.2.9.

Multidimensional array values can be built by nesting array constructors. In the inner constructors, the key word ARRAY can be omitted. For example, these produce the same result:

```
SELECT ARRAY[ARRAY[1,2], ARRAY[3,4]];  
```

```
array
---------------
{{1,2},{3,4}}
(1 row)
```

```
SELECT ARRAY[[1,2],[3,4]];  
```

```
array
---------------
{{1,2},{3,4}}
(1 row)
```

Since multidimensional arrays must be rectangular, inner constructors at the same level must produce sub-arrays of identical dimensions. Any cast applied to the outer ARRAY constructor propagates automatically to all the inner constructors.

Multidimensional array constructor elements can be anything yielding an array of the proper kind, not only a sub-ARRAY construct. For example:

```
CREATE TABLE arr(f1 int[], f2 int[]);
```

```
INSERT INTO arr VALUES (ARRAY[[1,2],[3,4]], ARRAY[[5,6],[7,8]]);
```
You can construct an empty array, but since it's impossible to have an array with no type, you must explicitly cast your empty array to the desired type. For example:

```sql
SELECT ARRAY[]::integer[];
```

```
array
-------
{}
(1 row)
```

It is also possible to construct an array from the results of a subquery. In this form, the array constructor is written with the key word `ARRAY` followed by a parenthesized (not bracketed) subquery. For example:

```sql
SELECT ARRAY(SELECT oid FROM pg_proc WHERE proname LIKE 'bytea%');
```

```
array
------------------------------------------------------------------
(1 row)
```

```sql
SELECT ARRAY(SELECT ARRAY[i, i*2] FROM generate_series(1,5) AS a(i));
```

```
array
----------------------------------
{{1,2},{2,4},{3,6},{4,8},{5,10}}
(1 row)
```

The subquery must return a single column. If the subquery's output column is of a non-array type, the resulting one-dimensional array will have an element for each row in the subquery result, with an element type matching that of the subquery's output column. If the subquery's output column is of an array type, the result will be an array of the same type but one higher dimension; in this case all the subquery rows must yield arrays of identical dimensionality, else the result would not be rectangular.

The subscripts of an array value built with `ARRAY` always begin with one. For more information about arrays, see Section 8.15.

### 4.2.13. Row Constructors

A row constructor is an expression that builds a row value (also called a composite value) using values for its member fields. A row constructor consists of the key word `ROW`, a left parenthesis, zero or more expressions (separated by commas) for the row field values, and finally a right parenthesis. For example:

```sql
SELECT ROW(1,2.5,'this is a test');
```

The key word `ROW` is optional when there is more than one expression in the list.

A row constructor can include the syntax `rowvalue.*/`, which will be expanded to a list of the elements of the row value, just as occurs when the `.*` syntax is used at the top level of a `SELECT` list (see Section 8.16.5). For example, if table `t` has columns `f1` and `f2`, these are the same:

```sql
SELECT ROW(t.*, 42) FROM t;
SELECT ROW(t.f1, t.f2, 42) FROM t;
```

**Note**

Before PostgreSQL 8.2, the `.*` syntax was not expanded in row constructors, so that writing `ROW(t.*, 42)` created a two-field row whose first field was another row value. The new behavior
SQL Syntax

is usually more useful. If you need the old behavior of nested row values, write the inner row value without .*, for instance ROW(t, 42).

By default, the value created by a ROW expression is of an anonymous record type. If necessary, it can be cast to a named composite type — either the row type of a table, or a composite type created with CREATE TYPE AS. An explicit cast might be needed to avoid ambiguity. For example:

```
CREATE TABLE mytable(f1 int, f2 float, f3 text);

CREATE FUNCTION getf1(mytable) RETURNS int AS 'SELECT $1.f1' LANGUAGE SQL;
-- No cast needed since only one getf1() exists
SELECT getf1(ROW(1,2.5,'this is a test'));
getf1
-------
 1
(1 row)
```

```
CREATE TYPE myrowtype AS (f1 int, f2 text, f3 numeric);

CREATE FUNCTION getf1(myrowtype) RETURNS int AS 'SELECT $1.f1' LANGUAGE SQL;
-- Now we need a cast to indicate which function to call:
SELECT getf1(ROW(1,2.5,'this is a test'));
ERROR:  function getf1(record) is not unique
SELECT getf1(ROW(1,2.5,'this is a test')::mytable);
getf1
-------
 1
(1 row)
```

Row constructors can be used to build composite values to be stored in a composite-type table column, or to be passed to a function that accepts a composite parameter. Also, it is possible to compare two row values or test a row with IS NULL or IS NOT NULL, for example:

```
SELECT ROW(1,2.5,'this is a test') = ROW(1, 3, 'not the same');
SELECT ROW(table.*) IS NULL FROM table;  -- detect all-null rows
```

For more detail see Section 9.24. Row constructors can also be used in connection with subqueries, as discussed in Section 9.23.

### 4.2.14. Expression Evaluation Rules

The order of evaluation of subexpressions is not defined. In particular, the inputs of an operator or function are not necessarily evaluated left-to-right or in any other fixed order.

Furthermore, if the result of an expression can be determined by evaluating only some parts of it, then other subexpressions might not be evaluated at all. For instance, if one wrote:

```
SELECT true OR somefunc();
then somefunc() would (probably) not be called at all. The same would be the case if one wrote:
```
Note that this is not the same as the left-to-right “short-circuiting” of Boolean operators that is found in some programming languages.

As a consequence, it is unwise to use functions with side effects as part of complex expressions. It is particularly dangerous to rely on side effects or evaluation order in \texttt{WHERE} and \texttt{HAVING} clauses, since those clauses are extensively reprocessed as part of developing an execution plan. Boolean expressions (\texttt{AND}/\texttt{OR}/\texttt{NOT} combinations) in those clauses can be reorganized in any manner allowed by the laws of Boolean algebra.

When it is essential to force evaluation order, a \texttt{CASE} construct (see Section 9.18) can be used. For example, this is an untrustworthy way of trying to avoid division by zero in a \texttt{WHERE} clause:

\begin{verbatim}
SELECT ... WHERE x > 0 AND y/x > 1.5;
\end{verbatim}

\begin{verbatim}
But this is safe:
SELECT ... WHERE CASE WHEN x > 0 THEN y/x > 1.5 ELSE false END;
\end{verbatim}

A \texttt{CASE} construct used in this fashion will defeat optimization attempts, so it should only be done when necessary. (In this particular example, it would be better to sidestep the problem by writing $y > 1.5 \times x$ instead.)

\texttt{CASE} is not a cure-all for such issues, however. One limitation of the technique illustrated above is that it does not prevent early evaluation of constant subexpressions. As described in Section 36.7, functions and operators marked \texttt{IMMUTABLE} can be evaluated when the query is planned rather than when it is executed. Thus for example

\begin{verbatim}
SELECT CASE WHEN x > 0 THEN 1/0 END FROM tab;
\end{verbatim}

is likely to result in a division-by-zero failure due to the planner trying to simplify the constant subexpression, even if every row in the table has $x > 0$ so that the \texttt{ELSE} arm would never be entered at run time.

While that particular example might seem silly, related cases that don't obviously involve constants can occur in queries executed within functions, since the values of function arguments and local variables can be inserted into queries as constants for planning purposes. Within PL/pgSQL functions, for example, using an \texttt{IF-THEN-ELSE} statement to protect a risky computation is much safer than just nesting it in a \texttt{CASE} expression.

Another limitation of the same kind is that a \texttt{CASE} cannot prevent evaluation of an aggregate expression contained within it, because aggregate expressions are computed before other expressions in a \texttt{SELECT} list or \texttt{HAVING} clause are considered. For example, the following query can cause a division-by-zero error despite seemingly having protected against it:

\begin{verbatim}
SELECT CASE WHEN min(employees) > 0
               THEN avg(expenses / employees)
     END
     FROM departments;
\end{verbatim}

The \texttt{min()} and \texttt{avg()} aggregates are computed concurrently over all the input rows, so if any row has \texttt{employees} equal to zero, the division-by-zero error will occur before there is any opportunity to test the result of \texttt{min()}. Instead, use a \texttt{WHERE} or \texttt{FILTER} clause to prevent problematic input rows from reaching an aggregate function in the first place.

4.3. Calling Functions

Postgres Pro allows functions that have named parameters to be called using either \texttt{positional} or \texttt{named} notation. Named notation is especially useful for functions that have a large number of parameters, since it makes the associations between parameters and actual arguments more explicit and reliable. In positional notation, a function call is written with its argument values in the same order as they are defined in the function declaration. In named notation, the arguments are matched to the function
parameters by name and can be written in any order. For each notation, also consider the effect of function argument types, documented in Section 10.3.

In either notation, parameters that have default values given in the function declaration need not be written in the call at all. But this is particularly useful in named notation, since any combination of parameters can be omitted; while in positional notation parameters can only be omitted from right to left.

Postgres Pro also supports mixed notation, which combines positional and named notation. In this case, positional parameters are written first and named parameters appear after them.

The following examples will illustrate the usage of all three notations, using the following function definition:

```sql
CREATE FUNCTION concat_lower_or_upper(a text, b text, uppercase boolean DEFAULT false)
RETURNS text
AS
$$
SELECT CASE
  WHEN $3 THEN UPPER($1 || ' ' || $2)
  ELSE LOWER($1 || ' ' || $2)
END;
$$
LANGUAGE SQL IMMUTABLE STRICT;
```

Function `concat_lower_or_upper` has two mandatory parameters, `a` and `b`. Additionally there is one optional parameter `uppercase` which defaults to `false`. The `a` and `b` inputs will be concatenated, and forced to either upper or lower case depending on the `uppercase` parameter. The remaining details of this function definition are not important here (see Chapter 36 for more information).

### 4.3.1. Using Positional Notation

Positional notation is the traditional mechanism for passing arguments to functions in Postgres Pro. An example is:

```sql
SELECT concat_lower_or_upper('Hello', 'World', true);
```

```sql
<table>
<thead>
<tr>
<th>concat_lower_or_upper</th>
</tr>
</thead>
<tbody>
<tr>
<td>HELLO WORLD</td>
</tr>
</tbody>
</table>
```

All arguments are specified in order. The result is upper case since `uppercase` is specified as `true`. Another example is:

```sql
SELECT concat_lower_or_upper('Hello', 'World');
```

```sql
<table>
<thead>
<tr>
<th>concat_lower_or_upper</th>
</tr>
</thead>
<tbody>
<tr>
<td>hello world</td>
</tr>
</tbody>
</table>
```

Here, the `uppercase` parameter is omitted, so it receives its default value of `false`, resulting in lower case output. In positional notation, arguments can be omitted from right to left so long as they have defaults.

### 4.3.2. Using Named Notation

In named notation, each argument's name is specified using `=>` to separate it from the argument expression. For example:

```sql
SELECT concat_lower_or_upper(a => 'Hello', b => 'World');
```

```sql
<table>
<thead>
<tr>
<th>concat_lower_or_upper</th>
</tr>
</thead>
<tbody>
<tr>
<td>hello world</td>
</tr>
</tbody>
</table>
```

41
Again, the argument `uppercase` was omitted so it is set to `false` implicitly. One advantage of using named notation is that the arguments may be specified in any order, for example:

```sql
SELECT concat_lower_or_upper(a => 'Hello', b => 'World', uppercase => true);
```

```
HELLO WORLD
(1 row)
```

```sql
SELECT concat_lower_or_upper(a => 'Hello', uppercase => true, b => 'World');
```

```
HELLO WORLD
(1 row)
```

An older syntax based on `":="` is supported for backward compatibility:

```sql
SELECT concat_lower_or_upper(a := 'Hello', uppercase := true, b := 'World');
```

```
HELLO WORLD
(1 row)
```

**4.3.3. Using Mixed Notation**

The mixed notation combines positional and named notation. However, as already mentioned, named arguments cannot precede positional arguments. For example:

```sql
SELECT concat_lower_or_upper('Hello', 'World', uppercase => true);
```

```
HELLO WORLD
(1 row)
```

In the above query, the arguments `a` and `b` are specified positionally, while `uppercase` is specified by name. In this example, that adds little except documentation. With a more complex function having numerous parameters that have default values, named or mixed notation can save a great deal of writing and reduce chances for error.

---

**Note**

Named and mixed call notations currently cannot be used when calling an aggregate function (but they do work when an aggregate function is used as a window function).
Chapter 5. Data Definition

This chapter covers how one creates the database structures that will hold one's data. In a relational database, the raw data is stored in tables, so the majority of this chapter is devoted to explaining how tables are created and modified and what features are available to control what data is stored in the tables. Subsequently, we discuss how tables can be organized into schemas, and how privileges can be assigned to tables. Finally, we will briefly look at other features that affect the data storage, such as inheritance, table partitioning, views, functions, and triggers.

5.1. Table Basics

A table in a relational database is much like a table on paper: It consists of rows and columns. The number and order of the columns is fixed, and each column has a name. The number of rows is variable — it reflects how much data is stored at a given moment. SQL does not make any guarantees about the order of the rows in a table. When a table is read, the rows will appear in an unspecified order, unless sorting is explicitly requested. This is covered in Chapter 7. Furthermore, SQL does not assign unique identifiers to rows, so it is possible to have several completely identical rows in a table. This is a consequence of the mathematical model that underlies SQL but is usually not desirable. Later in this chapter we will see how to deal with this issue.

Each column has a data type. The data type constrains the set of possible values that can be assigned to a column and assigns semantics to the data stored in the column so that it can be used for computations. For instance, a column declared to be of a numerical type will not accept arbitrary text strings, and the data stored in such a column can be used for mathematical computations. By contrast, a column declared to be of a character string type will accept almost any kind of data but it does not lend itself to mathematical calculations, although other operations such as string concatenation are available.

Postgres Pro includes a sizable set of built-in data types that fit many applications. Users can also define their own data types. Most built-in data types have obvious names and semantics, so we defer a detailed explanation to Chapter 8. Some of the frequently used data types are integer for whole numbers, numeric for possibly fractional numbers, text for character strings, date for dates, time for time-of-day values, and timestamp for values containing both date and time.

To create a table, you use the aptly named CREATE TABLE command. In this command you specify at least a name for the new table, the names of the columns and the data type of each column. For example:

```
CREATE TABLE my_first_table (  
    first_column text,  
    second_column integer
);
```

This creates a table named my_first_table with two columns. The first column is named first_column and has a data type of text; the second column has the name second_column and the type integer. The table and column names follow the identifier syntax explained in Section 4.1.1. The type names are usually also identifiers, but there are some exceptions. Note that the column list is comma-separated and surrounded by parentheses.

Of course, the previous example was heavily contrived. Normally, you would give names to your tables and columns that convey what kind of data they store. So let’s look at a more realistic example:

```
CREATE TABLE products (  
    product_no integer,  
    name text,  
    price numeric
);
```

(The numeric type can store fractional components, as would be typical of monetary amounts.)
There is a limit on how many columns a table can contain. Depending on the column types, it is between 250 and 1600. However, defining a table with anywhere near this many columns is highly unusual and often a questionable design.

If you no longer need a table, you can remove it using the DROP TABLE command. For example:

```
DROP TABLE my_first_table;
DROP TABLE products;
```

Attempting to drop a table that does not exist is an error. Nevertheless, it is common in SQL script files to unconditionally try to drop each table before creating it, ignoring any error messages, so that the script works whether or not the table exists. (If you like, you can use the `DROP TABLE IF EXISTS` variant to avoid the error messages, but this is not standard SQL.)

If you need to modify a table that already exists, see Section 5.6 later in this chapter.

With the tools discussed so far you can create fully functional tables. The remainder of this chapter is concerned with adding features to the table definition to ensure data integrity, security, or convenience. If you are eager to fill your tables with data now you can skip ahead to Chapter 6 and read the rest of this chapter later.

### 5.2. Default Values

A column can be assigned a default value. When a new row is created and no values are specified for some of the columns, those columns will be filled with their respective default values. A data manipulation command can also request explicitly that a column be set to its default value, without having to know what that value is. (Details about data manipulation commands are in Chapter 6.)

If no default value is declared explicitly, the default value is the null value. This usually makes sense because a null value can be considered to represent unknown data.

In a table definition, default values are listed after the column data type. For example:

```
CREATE TABLE products (  
    product_no integer,  
    name text,  
    price numeric DEFAULT 9.99  
);  
```

The default value can be an expression, which will be evaluated whenever the default value is inserted (not when the table is created). A common example is for a timestamp column to have a default of `CURRENT_TIMESTAMP`, so that it gets set to the time of row insertion. Another common example is generating a “serial number” for each row. In Postgres Pro this is typically done by something like:

```
CREATE TABLE products (  
    product_no integer DEFAULT nextval('products_product_no_seq'),  
    ...  
);  
```

where the `nextval()` function supplies successive values from a sequence object (see Section 9.17). This arrangement is sufficiently common that there’s a special shorthand for it:

```
CREATE TABLE products (  
    product_no SERIAL,  
    ...  
);  
```
The SERIAL shorthand is discussed further in Section 8.1.4.

5.3. Generated Columns

A generated column is a special column that is always computed from other columns. Thus, it is for columns what a view is for tables. There are two kinds of generated columns: stored and virtual. A stored generated column is computed when it is written (inserted or updated) and occupies storage as if it were a normal column. A virtual generated column occupies no storage and is computed when it is read. Thus, a virtual generated column is similar to a view and a stored generated column is similar to a materialized view (except that it is always updated automatically). Postgres Pro currently implements only stored generated columns.

To create a generated column, use the GENERATED ALWAYS AS clause in CREATE TABLE, for example:

```sql
CREATE TABLE people (  
  ...,  
  height_cm numeric,  
  height_in numeric GENERATED ALWAYS AS (height_cm / 2.54) STORED
);  
```

The keyword STORED must be specified to choose the stored kind of generated column. See CREATE TABLE for more details.

A generated column cannot be written to directly. In INSERT or UPDATE commands, a value cannot be specified for a generated column, but the keyword DEFAULT may be specified.

Consider the differences between a column with a default and a generated column. The column default is evaluated once when the row is first inserted if no other value was provided; a generated column is updated whenever the row changes and cannot be overridden. A column default may not refer to other columns of the table; a generation expression would normally do so. A column default can use volatile functions, for example random() or functions referring to the current time; this is not allowed for generated columns.

Several restrictions apply to the definition of generated columns and tables involving generated columns:

- The generation expression can only use immutable functions and cannot use subqueries or reference anything other than the current row in any way.
- A generation expression cannot reference another generated column.
- A generation expression cannot reference a system column, except tableoid.
- A generated column cannot have a column default or an identity definition.
- A generated column cannot be part of a partition key.
- Foreign tables can have generated columns. See CREATE FOREIGN TABLE for details.
- For inheritance:
  - If a parent column is a generated column, a child column must also be a generated column using the same expression. In the definition of the child column, leave off the GENERATED clause, as it will be copied from the parent.
  - In case of multiple inheritance, if one parent column is a generated column, then all parent columns must be generated columns and with the same expression.
  - If a parent column is not a generated column, a child column may be defined to be a generated column or not.

Additional considerations apply to the use of generated columns.
• Generated columns maintain access privileges separately from their underlying base columns. So, it is possible to arrange it so that a particular role can read from a generated column but not from the underlying base columns.

• Generated columns are, conceptually, updated after **BEFORE** triggers have run. Therefore, changes made to base columns in a **BEFORE** trigger will be reflected in generated columns. But conversely, it is not allowed to access generated columns in **BEFORE** triggers.

### 5.4. Constraints

Data types are a way to limit the kind of data that can be stored in a table. For many applications, however, the constraint they provide is too coarse. For example, a column containing a product price should probably only accept positive values. But there is no standard data type that accepts only positive numbers. Another issue is that you might want to constrain column data with respect to other columns or rows. For example, in a table containing product information, there should be only one row for each product number.

To that end, SQL allows you to define constraints on columns and tables. Constraints give you as much control over the data in your tables as you wish. If a user attempts to store data in a column that would violate a constraint, an error is raised. This applies even if the value came from the default value definition.

#### 5.4.1. Check Constraints

A check constraint is the most generic constraint type. It allows you to specify that the value in a certain column must satisfy a Boolean (truth-value) expression. For instance, to require positive product prices, you could use:

```sql
CREATE TABLE products (  
    product_no integer,  
    name text,  
    price numeric CHECK (price > 0)
);
```

As you see, the constraint definition comes after the data type, just like default value definitions. Default values and constraints can be listed in any order. A check constraint consists of the key word **CHECK** followed by an expression in parentheses. The check constraint expression should involve the column thus constrained, otherwise the constraint would not make too much sense.

You can also give the constraint a separate name. This clarifies error messages and allows you to refer to the constraint when you need to change it. The syntax is:

```sql
CREATE TABLE products (  
    product_no integer,  
    name text,  
    price numeric CONSTRAINT positive_price CHECK (price > 0)
);
```

So, to specify a named constraint, use the key word **CONSTRAINT** followed by an identifier followed by the constraint definition. (If you don't specify a constraint name in this way, the system chooses a name for you.)

A check constraint can also refer to several columns. Say you store a regular price and a discounted price, and you want to ensure that the discounted price is lower than the regular price:

```sql
CREATE TABLE products (  
    product_no integer,  
    name text,  
    price numeric CHECK (price > 0),  
    discounted_price numeric CHECK (discounted_price > 0),  
    CHECK (price > discounted_price)
);
```
The first two constraints should look familiar. The third one uses a new syntax. It is not attached to a particular column, instead it appears as a separate item in the comma-separated column list. Column definitions and these constraint definitions can be listed in mixed order.

We say that the first two constraints are column constraints, whereas the third one is a table constraint because it is written separately from any one column definition. Column constraints can also be written as table constraints, while the reverse is not necessarily possible, since a column constraint is supposed to refer to only the column it is attached to. (Postgres Pro doesn't enforce that rule, but you should follow it if you want your table definitions to work with other database systems.) The above example could also be written as:

```sql
CREATE TABLE products (
    product_no integer,
    name text,
    price numeric,
    CHECK (price > 0),
    discounted_price numeric,
    CHECK (discounted_price > 0),
    CHECK (price > discounted_price)
);
```

or even:

```sql
CREATE TABLE products (
    product_no integer,
    name text,
    price numeric CHECK (price > 0),
    discounted_price numeric,
    CHECK (discounted_price > 0 AND price > discounted_price)
);
```

It's a matter of taste.

Names can be assigned to table constraints in the same way as column constraints:

```sql
CREATE TABLE products (
    product_no integer,
    name text,
    price numeric,
    CHECK (price > 0),
    discounted_price numeric,
    CHECK (discounted_price > 0),
    CONSTRAINT valid_discount CHECK (price > discounted_price)
);
```

It should be noted that a check constraint is satisfied if the check expression evaluates to true or the null value. Since most expressions will evaluate to the null value if any operand is null, they will not prevent null values in the constrained columns. To ensure that a column does not contain null values, the not-null constraint described in the next section can be used.

Note

Postgres Pro does not support CHECK constraints that reference table data other than the new or updated row being checked. While a CHECK constraint that violates this rule may appear to work in simple tests, it cannot guarantee that the database will not reach a state in which the constraint condition is false (due to subsequent changes of the other row(s) involved). This would cause a database dump and reload to fail. The reload could fail even when the complete database state is consistent with the constraint, due to rows not being loaded in an order that will satisfy the
constraint. If possible, use **UNIQUE**, **EXCLUDE**, or **FOREIGN KEY** constraints to express cross-row and cross-table restrictions.

If what you desire is a one-time check against other rows at row insertion, rather than a continuously-maintained consistency guarantee, a custom trigger can be used to implement that. (This approach avoids the dump/reload problem because pg_dump does not reinstall triggers until after reloading data, so that the check will not be enforced during a dump/reload.)

**Note**

Postgres Pro assumes that **CHECK** constraints' conditions are immutable, that is, they will always give the same result for the same input row. This assumption is what justifies examining **CHECK** constraints only when rows are inserted or updated, and not at other times. (The warning above about not referencing other table data is really a special case of this restriction.)

An example of a common way to break this assumption is to reference a user-defined function in a **CHECK** expression, and then change the behavior of that function. Postgres Pro does not disallow that, but it will not notice if there are rows in the table that now violate the **CHECK** constraint. That would cause a subsequent database dump and reload to fail. The recommended way to handle such a change is to drop the constraint (using **ALTER TABLE**), adjust the function definition, and re-add the constraint, thereby rechecking it against all table rows.

### 5.4.2. Not-Null Constraints

A not-null constraint simply specifies that a column must not assume the null value. A syntax example:

```sql
CREATE TABLE products (
    product_no integer NOT NULL,
    name text NOT NULL,
    price numeric
);
```

A not-null constraint is always written as a column constraint. A not-null constraint is functionally equivalent to creating a check constraint **CHECK** *(column_name IS NOT NULL)*, but in Postgres Pro creating an explicit not-null constraint is more efficient. The drawback is that you cannot give explicit names to not-null constraints created this way.

Of course, a column can have more than one constraint. Just write the constraints one after another:

```sql
CREATE TABLE products (
    product_no integer NOT NULL,
    name text NOT NULL,
    price numeric NOT NULL CHECK (price > 0)
);
```

The order doesn’t matter. It does not necessarily determine in which order the constraints are checked.

The **NOT NULL** constraint has an inverse: the **NULL** constraint. This does not mean that the column must be null, which would surely be useless. Instead, this simply selects the default behavior that the column might be null. The **NULL** constraint is not present in the SQL standard and should not be used in portable applications. (It was only added to Postgres Pro to be compatible with some other database systems.) Some users, however, like it because it makes it easy to toggle the constraint in a script file. For example, you could start with:

```sql
CREATE TABLE products (
    product_no integer NULL,
    name text NULL,
    price numeric NULL
);
and then insert the **NOT** key word where desired.

**Tip**
In most database designs the majority of columns should be marked not null.

### 5.4.3. Unique Constraints

Unique constraints ensure that the data contained in a column, or a group of columns, is unique among all the rows in the table. The syntax is:

```sql
CREATE TABLE products (  
    product_no integer **UNIQUE**,  
    name text,  
    price numeric
);
```

when written as a column constraint, and:

```sql
CREATE TABLE products (  
    product_no integer,  
    name text,  
    price numeric,  
    **UNIQUE** (product_no)
);
```

when written as a table constraint.

To define a unique constraint for a group of columns, write it as a table constraint with the column names separated by commas:

```sql
CREATE TABLE example (  
    a integer,  
    b integer,  
    c integer,  
    **UNIQUE** (a, c)
);
```

This specifies that the combination of values in the indicated columns is unique across the whole table, though any one of the columns need not be (and ordinarily isn't) unique.

You can assign your own name for a unique constraint, in the usual way:

```sql
CREATE TABLE products (  
    product_no integer **CONSTRAINT must_be_different** **UNIQUE**,  
    name text,  
    price numeric
);
```

Adding a unique constraint will automatically create a unique B-tree index on the column or group of columns listed in the constraint. A uniqueness restriction covering only some rows cannot be written as a unique constraint, but it is possible to enforce such a restriction by creating a unique **partial index**.

In general, a unique constraint is violated if there is more than one row in the table where the values of all of the columns included in the constraint are equal. However, two null values are never considered equal in this comparison. That means even in the presence of a unique constraint it is possible to store duplicate rows that contain a null value in at least one of the constrained columns. This behavior conforms to the SQL standard, but we have heard that other SQL databases might not follow this rule. So be careful when developing applications that are intended to be portable.
5.4.4. Primary Keys

A primary key constraint indicates that a column, or group of columns, can be used as a unique identifier for rows in the table. This requires that the values be both unique and not null. So, the following two table definitions accept the same data:

```
CREATE TABLE products (  
    product_no integer UNIQUE NOT NULL,  
    name text,  
    price numeric  
);  
CREATE TABLE products (  
    product_no integer PRIMARY KEY,  
    name text,  
    price numeric  
);  
```

Primary keys can span more than one column; the syntax is similar to unique constraints:

```
CREATE TABLE example (  
    a integer,  
    b integer,  
    c integer,  
    PRIMARY KEY (a, c)  
);  
```

Adding a primary key will automatically create a unique B-tree index on the column or group of columns listed in the primary key, and will force the column(s) to be marked NOT NULL.

A table can have at most one primary key. (There can be any number of unique and not-null constraints, which are functionally almost the same thing, but only one can be identified as the primary key.) Relational database theory dictates that every table must have a primary key. This rule is not enforced by Postgres Pro, but it is usually best to follow it.

Primary keys are useful both for documentation purposes and for client applications. For example, a GUI application that allows modifying row values probably needs to know the primary key of a table to be able to identify rows uniquely. There are also various ways in which the database system makes use of a primary key if one has been declared; for example, the primary key defines the default target column(s) for foreign keys referencing its table.

5.4.5. Foreign Keys

A foreign key constraint specifies that the values in a column (or a group of columns) must match the values appearing in some row of another table. We say this maintains the referential integrity between two related tables.

Say you have the product table that we have used several times already:

```
CREATE TABLE products (  
    product_no integer PRIMARY KEY,  
    name text,  
    price numeric  
);  
```

Let's also assume you have a table storing orders of those products. We want to ensure that the orders table only contains orders of products that actually exist. So we define a foreign key constraint in the orders table that references the products table:

```
CREATE TABLE orders (  
    order_id integer PRIMARY KEY,  
    product_no integer REFERENCES products (product_no),  
);  
```
Now it is impossible to create orders with non-NULL `product_no` entries that do not appear in the products table.

We say that in this situation the orders table is the *referencing* table and the products table is the *referenced* table. Similarly, there are referencing and referenced columns.

You can also shorten the above command to:

```
CREATE TABLE orders (
    order_id integer PRIMARY KEY,
    product_no integer REFERENCES products,
    quantity integer
);
```

because in absence of a column list the primary key of the referenced table is used as the referenced column(s).

You can assign your own name for a foreign key constraint, in the usual way.

A foreign key can also constrain and reference a group of columns. As usual, it then needs to be written in table constraint form. Here is a contrived syntax example:

```
CREATE TABLE t1 (
    a integer PRIMARY KEY,
    b integer,
    c integer,
    FOREIGN KEY (b, c) REFERENCES other_table (c1, c2)
);
```

Of course, the number and type of the constrained columns need to match the number and type of the referenced columns.

Sometimes it is useful for the “other table” of a foreign key constraint to be the same table; this is called a *self-referential* foreign key. For example, if you want rows of a table to represent nodes of a tree structure, you could write

```
CREATE TABLE tree (
    node_id integer PRIMARY KEY,
    parent_id integer REFERENCES tree,
    name text,
    ...
);
```

A top-level node would have NULL `parent_id`, while non-NULL `parent_id` entries would be constrained to reference valid rows of the table.

A table can have more than one foreign key constraint. This is used to implement many-to-many relationships between tables. Say you have tables about products and orders, but now you want to allow one order to contain possibly many products (which the structure above did not allow). You could use this table structure:

```
CREATE TABLE products (
    product_no integer PRIMARY KEY,
    name text,
    price numeric
);

CREATE TABLE orders (
    order_id integer PRIMARY KEY,
    shipping_address text,
    ...
CREATE TABLE order_items (  product_no integer REFERENCES products,  order_id integer REFERENCES orders,  quantity integer,  PRIMARY KEY (product_no, order_id) );

Notice that the primary key overlaps with the foreign keys in the last table.

We know that the foreign keys disallow creation of orders that do not relate to any products. But what if a product is removed after an order is created that references it? SQL allows you to handle that as well. Intuitively, we have a few options:

- Disallow deleting a referenced product
- Delete the orders as well
- Something else?

To illustrate this, let's implement the following policy on the many-to-many relationship example above: when someone wants to remove a product that is still referenced by an order (via order_items), we disallow it. If someone removes an order, the order items are removed as well:

CREATE TABLE products (  product_no integer PRIMARY KEY,  name text,  price numeric );

CREATE TABLE orders (  order_id integer PRIMARY KEY,  shipping_address text,  ... );

CREATE TABLE order_items (  product_no integer REFERENCES products ON DELETE RESTRICT,  order_id integer REFERENCES orders ON DELETE CASCADE,  quantity integer,  PRIMARY KEY (product_no, order_id) );

Restricting and cascading deletes are the two most common options. RESTRICT prevents deletion of a referenced row. NO ACTION means that if any referencing rows still exist when the constraint is checked, an error is raised; this is the default behavior if you do not specify anything. (The essential difference between these two choices is that NO ACTION allows the check to be deferred until later in the transaction, whereas RESTRICT does not.) CASCADE specifies that when a referenced row is deleted, row(s) referencing it should be automatically deleted as well. There are two other options: SET NULL and SET DEFAULT. These cause the referencing column(s) in the referencing row(s) to be set to nulls or their default values, respectively, when the referenced row is deleted. Note that these do not excuse you from observing any constraints. For example, if an action specifies SET DEFAULT but the default value would not satisfy the foreign key constraint, the operation will fail.

Analogous to ON DELETE there is also ON UPDATE which is invoked when a referenced column is changed (updated). The possible actions are the same. In this case, CASCADE means that the updated values of the referenced column(s) should be copied into the referencing row(s).

Normally, a referencing row need not satisfy the foreign key constraint if any of its referencing columns are null. If MATCH FULL is added to the foreign key declaration, a referencing row escapes satisfying the
constraint only if all its referencing columns are null (so a mix of null and non-null values is guaranteed to fail a MATCH FULL constraint). If you don't want referencing rows to be able to avoid satisfying the foreign key constraint, declare the referencing column(s) as NOT NULL.

A foreign key must reference columns that either are a primary key or form a unique constraint. This means that the referenced columns always have an index (the one underlying the primary key or unique constraint); so checks on whether a referencing row has a match will be efficient. Since a DELETE of a row from the referenced table or an UPDATE of a referenced column will require a scan of the referencing table for rows matching the old value, it is often a good idea to index the referencing columns too. Because this is not always needed, and there are many choices available on how to index, declaration of a foreign key constraint does not automatically create an index on the referencing columns.

More information about updating and deleting data is in Chapter 6. Also see the description of foreign key constraint syntax in the reference documentation for CREATE TABLE.

### 5.4.6. Exclusion Constraints

Exclusion constraints ensure that if any two rows are compared on the specified columns or expressions using the specified operators, at least one of these operator comparisons will return false or null. The syntax is:

```sql
CREATE TABLE circles (
    c circle,
    EXCLUDE USING gist (c WITH &&)
);
```

See also CREATE TABLE ... CONSTRAINT ... EXCLUDE for details.

Adding an exclusion constraint will automatically create an index of the type specified in the constraint declaration.

### 5.5. System Columns

Every table has several system columns that are implicitly defined by the system. Therefore, these names cannot be used as names of user-defined columns. (Note that these restrictions are separate from whether the name is a key word or not; quoting a name will not allow you to escape these restrictions.) You do not really need to be concerned about these columns; just know they exist.

- **tableoid**
  The OID of the table containing this row. This column is particularly handy for queries that select from partitioned tables (see Section 5.11) or inheritance hierarchies (see Section 5.10), since without it, it's difficult to tell which individual table a row came from. The tableoid can be joined against the oid column of pg_class to obtain the table name.

- **xmin**
  The identity (transaction ID) of the inserting transaction for this row version. (A row version is an individual state of a row; each update of a row creates a new row version for the same logical row.)

- **cmin**
  The command identifier (starting at zero) within the inserting transaction.

- **xmax**
  The identity (transaction ID) of the deleting transaction, or zero for an undeleted row version. It is possible for this column to be nonzero in a visible row version. That usually indicates that the deleting transaction hasn't committed yet, or that an attempted deletion was rolled back.

- **cmax**
The command identifier within the deleting transaction, or zero.

ctid

The physical location of the row version within its table. Note that although the ctid can be used to locate the row version very quickly, a row's ctid will change if it is updated or moved by VACUUM FULL. Therefore ctid is useless as a long-term row identifier. A primary key should be used to identify logical rows.

Transaction identifiers are also 32-bit quantities. In a long-lived database it is possible for transaction IDs to wrap around. This is not a fatal problem given appropriate maintenance procedures; see Chapter 23 for details. It is unwise, however, to depend on the uniqueness of transaction IDs over the long term (more than one billion transactions).

Command identifiers are also 32-bit quantities. This creates a hard limit of $2^{32}$ (4 billion) SQL commands within a single transaction. In practice this limit is not a problem — note that the limit is on the number of SQL commands, not the number of rows processed. Also, only commands that actually modify the database contents will consume a command identifier.

5.6. Modifying Tables

When you create a table and you realize that you made a mistake, or the requirements of the application change, you can drop the table and create it again. But this is not a convenient option if the table is already filled with data, or if the table is referenced by other database objects (for instance a foreign key constraint). Therefore Postgres Pro provides a family of commands to make modifications to existing tables. Note that this is conceptually distinct from altering the data contained in the table: here we are interested in altering the definition, or structure, of the table.

You can:
- Add columns
- Remove columns
- Add constraints
- Remove constraints
- Change default values
- Change column data types
- Rename columns
- Rename tables

All these actions are performed using the ALTER TABLE command, whose reference page contains details beyond those given here.

5.6.1. Adding a Column

To add a column, use a command like:

```
ALTER TABLE products ADD COLUMN description text;
```

The new column is initially filled with whatever default value is given (null if you don't specify a DEFAULT clause).

**Tip**

From Postgres Pro 11, adding a column with a constant default value no longer means that each row of the table needs to be updated when the ALTER TABLE statement is executed. Instead, the default value will be returned the next time the row is accessed, and applied when the table is rewritten, making the ALTER TABLE very fast even on large tables.

However, if the default value is volatile (e.g., `clock_timestamp()`) each row will need to be updated with the value calculated at the time ALTER TABLE is executed. To avoid a potentially lengthy update operation, particularly if you intend to fill the column with mostly nondefault values anyway, it
may be preferable to add the column with no default, insert the correct values using \texttt{UPDATE}, and then add any desired default as described below.

You can also define constraints on the column at the same time, using the usual syntax:

\texttt{ALTER TABLE products ADD COLUMN description text CHECK (description <> '');}

In fact all the options that can be applied to a column description in \texttt{CREATE TABLE} can be used here. Keep in mind however that the default value must satisfy the given constraints, or the \texttt{ADD} will fail. Alternatively, you can add constraints later (see below) after you've filled in the new column correctly.

5.6.2. Removing a Column

To remove a column, use a command like:

\texttt{ALTER TABLE products DROP COLUMN description;}

Whatever data was in the column disappears. Table constraints involving the column are dropped, too. However, if the column is referenced by a foreign key constraint of another table, Postgres Pro will not silently drop that constraint. You can authorize dropping everything that depends on the column by adding \texttt{CASCADE}:

\texttt{ALTER TABLE products DROP COLUMN description CASCADE;}

See Section 5.14 for a description of the general mechanism behind this.

5.6.3. Adding a Constraint

To add a constraint, the table constraint syntax is used. For example:

\texttt{ALTER TABLE products ADD CHECK (name <> '');}
\texttt{ALTER TABLE products ADD CONSTRAINT some_name UNIQUE (product_no);}
\texttt{ALTER TABLE products ADD FOREIGN KEY (product_group_id) REFERENCES product_groups;}

To add a not-null constraint, which cannot be written as a table constraint, use this syntax:

\texttt{ALTER TABLE products ALTER COLUMN product_no SET NOT NULL;}

The constraint will be checked immediately, so the table data must satisfy the constraint before it can be added.

5.6.4. Removing a Constraint

To remove a constraint you need to know its name. If you gave it a name then that's easy. Otherwise the system assigned a generated name, which you need to find out. The \texttt{psql} command \texttt{\textbackslash d tablename} can be helpful here; other interfaces might also provide a way to inspect table details. Then the command is:

\texttt{ALTER TABLE products DROP CONSTRAINT some_name;}

(If you are dealing with a generated constraint name like $2$, don't forget that you'll need to double-quote it to make it a valid identifier.)

As with dropping a column, you need to add \texttt{CASCADE} if you want to drop a constraint that something else depends on. An example is that a foreign key constraint depends on a unique or primary key constraint on the referenced column(s).

This works the same for all constraint types except not-null constraints. To drop a not null constraint use:

\texttt{ALTER TABLE products ALTER COLUMN product_no DROP NOT NULL;}

(Recall that not-null constraints do not have names.)

5.6.5. Changing a Column's Default Value

To set a new default for a column, use a command like:

\texttt{ALTER TABLE products ALTER COLUMN price SET DEFAULT 7.77;}

55
Note that this doesn’t affect any existing rows in the table, it just changes the default for future INSERT commands.

To remove any default value, use:

```sql
ALTER TABLE products ALTER COLUMN price DROP DEFAULT;
```

This is effectively the same as setting the default to null. As a consequence, it is not an error to drop a default where one hadn’t been defined, because the default is implicitly the null value.

### 5.6.6. Changing a Column's Data Type

To convert a column to a different data type, use a command like:

```sql
ALTER TABLE products ALTER COLUMN price TYPE numeric(10,2);
```

This will succeed only if each existing entry in the column can be converted to the new type by an implicit cast. If a more complex conversion is needed, you can add a `USING` clause that specifies how to compute the new values from the old.

Postgres Pro will attempt to convert the column’s default value (if any) to the new type, as well as any constraints that involve the column. But these conversions might fail, or might produce surprising results. It’s often best to drop any constraints on the column before altering its type, and then add back suitably modified constraints afterwards.

### 5.6.7. Renaming a Column

To rename a column:

```sql
ALTER TABLE products RENAME COLUMN product_no TO product_number;
```

### 5.6.8. Renaming a Table

To rename a table:

```sql
ALTER TABLE products RENAME TO items;
```

### 5.7. Privileges

When an object is created, it is assigned an owner. The owner is normally the role that executed the creation statement. For most kinds of objects, the initial state is that only the owner (or a superuser) can do anything with the object. To allow other roles to use it, privileges must be granted.

There are different kinds of privileges: SELECT, INSERT, UPDATE, DELETE, TRUNCATE, REFERENCES, TRIGGER, CREATE, CONNECT, TEMPORARY, EXECUTE, and USAGE. The privileges applicable to a particular object vary depending on the object’s type (table, function, etc). More detail about the meanings of these privileges appears below. The following sections and chapters will also show you how these privileges are used.

The right to modify or destroy an object is inherent in being the object's owner, and cannot be granted or revoked in itself. (However, like all privileges, that right can be inherited by members of the owning role; see Section 20.3.)

An object can be assigned to a new owner with an `ALTER` command of the appropriate kind for the object, for example

```sql
ALTER TABLE table_name OWNER TO new_owner;
```

Superusers can always do this; ordinary roles can only do it if they are both the current owner of the object (or a member of the owning role) and a member of the new owning role.

To assign privileges, the `GRANT` command is used. For example, if `joe` is an existing role, and `accounts` is an existing table, the privilege to update the table can be granted with:

```sql
GRANT UPDATE ON accounts TO joe;
```

Writing `ALL` in place of a specific privilege grants all privileges that are relevant for the object type.
The special “role” name **PUBLIC** can be used to grant a privilege to every role on the system. Also, “group” roles can be set up to help manage privileges when there are many users of a database — for details see Chapter 20.

To revoke a previously-granted privilege, use the fittingly named **REVOKE** command:

```
REVOKE ALL ON accounts FROM PUBLIC;
```

Ordinarily, only the object's owner (or a superuser) can grant or revoke privileges on an object. However, it is possible to grant a privilege “with grant option”, which gives the recipient the right to grant it in turn to others. If the grant option is subsequently revoked then all who received the privilege from that recipient (directly or through a chain of grants) will lose the privilege. For details see the **GRANT** and **REVOKE** reference pages.

An object’s owner can choose to revoke their own ordinary privileges, for example to make a table read-only for themselves as well as others. But owners are always treated as holding all grant options, so they can always re-grant their own privileges.

The available privileges are:

**SELECT**

- Allows `SELECT` from any column, or specific column(s), of a table, view, materialized view, or other table-like object. Also allows use of `COPY TO`. This privilege is also needed to reference existing column values in `UPDATE` or `DELETE`. For sequences, this privilege also allows use of the `currval` function. For large objects, this privilege allows the object to be read.

**INSERT**

- Allows `INSERT` of a new row into a table, view, etc. Can be granted on specific column(s), in which case only those columns may be assigned to in the `INSERT` command (other columns will therefore receive default values). Also allows use of `COPY FROM`.

**UPDATE**

- Allows `UPDATE` of any column, or specific column(s), of a table, view, etc. (In practice, any nontrivial `UPDATE` command will require `SELECT` privilege as well, since it must reference table columns to determine which rows to update, and/or to compute new values for columns.) `SELECT ... FOR UPDATE` and `SELECT ... FOR SHARE` also require this privilege on at least one column, in addition to the `SELECT` privilege. For sequences, this privilege allows use of the `nextval` and `setval` functions. For large objects, this privilege allows writing or truncating the object.

**DELETE**

- Allows `DELETE` of a row from a table, view, etc. (In practice, any nontrivial `DELETE` command will require `SELECT` privilege as well, since it must reference table columns to determine which rows to delete.)

**TRUNCATE**

- Allows `TRUNCATE` on a table.

**REFERENCES**

- Allows creation of a foreign key constraint referencing a table, or specific column(s) of a table.

**TRIGGER**

- Allows creation of a trigger on a table, view, etc.

**CREATE**

- For databases, allows new schemas and publications to be created within the database, and allows trusted extensions to be installed within the database.
For schemas, allows new objects to be created within the schema. To rename an existing object, you must own the object and have this privilege for the containing schema.

For tablespaces, allows tables, indexes, and temporary files to be created within the tablespace, and allows databases to be created that have the tablespace as their default tablespace.

Note that revoking this privilege will not alter the existence or location of existing objects.

CONNECT

Allows the grantee to connect to the database. This privilege is checked at connection startup (in addition to checking any restrictions imposed by `pg_hba.conf`).

TEMPORARY

Allows temporary tables to be created while using the database.

EXECUTE

Allows calling a function or procedure, including use of any operators that are implemented on top of the function. This is the only type of privilege that is applicable to functions and procedures.

USAGE

For procedural languages, allows use of the language for the creation of functions in that language. This is the only type of privilege that is applicable to procedural languages.

For schemas, allows access to objects contained in the schema (assuming that the objects' own privilege requirements are also met). Essentially this allows the grantee to "look up" objects within the schema. Without this permission, it is still possible to see the object names, e.g., by querying system catalogs. Also, after revoking this permission, existing sessions might have statements that have previously performed this lookup, so this is not a completely secure way to prevent object access.

For sequences, allows use of the `currval` and `nextval` functions.

For types and domains, allows use of the type or domain in the creation of tables, functions, and other schema objects. (Note that this privilege does not control all "usage" of the type, such as values of the type appearing in queries. It only prevents objects from being created that depend on the type. The main purpose of this privilege is controlling which users can create dependencies on a type, which could prevent the owner from changing the type later.)

For foreign-data wrappers, allows creation of new servers using the foreign-data wrapper.

For foreign servers, allows creation of foreign tables using the server. Grantees may also create, alter, or drop their own user mappings associated with that server.

The privileges required by other commands are listed on the reference page of the respective command.

Postgres Pro grants privileges on some types of objects to `PUBLIC` by default when the objects are created. No privileges are granted to `PUBLIC` by default on tables, table columns, sequences, foreign data wrappers, foreign servers, large objects, schemas, or tablespaces. For other types of objects, the default privileges granted to `PUBLIC` are as follows: `CONNECT` and `TEMPORARY` (create temporary tables) privileges for databases; `EXECUTE` privilege for functions and procedures; and `USAGE` privilege for languages and data types (including domains). The object owner can, of course, `REVOKE` both default and expressly granted privileges. (For maximum security, issue the `REVOKE` in the same transaction that creates the object; then there is no window in which another user can use the object.) Also, these default privilege settings can be overridden using the `ALTER DEFAULT PRIVILEGES` command.

Table 5.1 shows the one-letter abbreviations that are used for these privilege types in `ACL` (Access Control List) values. You will see these letters in the output of the `psql` commands listed below, or when looking at ACL columns of system catalogs.
Table 5.1. ACL Privilege Abbreviations

<table>
<thead>
<tr>
<th>Privilege</th>
<th>Abbreviation</th>
<th>Applicable Object Types</th>
</tr>
</thead>
<tbody>
<tr>
<td>SELECT</td>
<td>r (&quot;read&quot;)</td>

<td>U</td>
<td>\dT+</td>
</tr>
</tbody>
</table>

The privileges that have been granted for a particular object are displayed as a list of `aclitem` entries, where each `aclitem` describes the permissions of one grantee that have been granted by a particular grantor. For example, `calvin=r*w/hobbes` specifies that the role `calvin` has the privilege `SELECT (r)` with grant option (\*) as well as the non-grantable privilege `UPDATE (w)`, both granted by the role `hobbes`. If `calvin` also has some privileges on the same object granted by a different grantor, those would appear as a separate `aclitem` entry. An empty grantee field in an `aclitem` stands for `PUBLIC`.

As an example, suppose that user `miriam` creates table `mytable` and does:
Data Definition

GRANT SELECT ON mytable TO PUBLIC;
GRANT SELECT, UPDATE, INSERT ON mytable TO admin;
GRANT SELECT (col1), UPDATE (col1) ON mytable TO miriam_rw;

Then psql's \dp command would show:

=> \dp mytable

<table>
<thead>
<tr>
<th>Schema</th>
<th>Name</th>
<th>Type</th>
<th>Access privileges</th>
<th>Column privileges</th>
<th>Policies</th>
</tr>
</thead>
<tbody>
<tr>
<td>public</td>

<td>=r/miriam</td>
<td>miriam_rw=rw/miriam</td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>admin=arw/miriam</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

(1 row)

If the “Access privileges” column is empty for a given object, it means the object has default privileges (that is, its privileges entry in the relevant system catalog is null). Default privileges always include all privileges for the owner, and can include some privileges for PUBLIC depending on the object type, as explained above. The first GRANT or REVOKE on an object will instantiate the default privileges (producing, for example, miriam=arwdDxt/miriam) and then modify them per the specified request. Similarly, entries are shown in “Column privileges” only for columns with nondefault privileges. (Note: for this purpose, “default privileges” always means the built-in default privileges for the object's type. An object whose privileges have been affected by an ALTER DEFAULT PRIVILEGES command will always be shown with an explicit privilege entry that includes the effects of the ALTER.)

Notice that the owner's implicit grant options are not marked in the access privileges display. A * will appear only when grant options have been explicitly granted to someone.

5.8. Row Security Policies

In addition to the SQL-standard privilege system available through GRANT, tables can have row security policies that restrict, on a per-user basis, which rows can be returned by normal queries or inserted, updated, or deleted by data modification commands. This feature is also known as Row-Level Security. By default, tables do not have any policies, so that if a user has access privileges to a table according to the SQL privilege system, all rows within it are equally available for querying or updating.

When row security is enabled on a table (with ALTER TABLE ... ENABLE ROW LEVEL SECURITY), all normal access to the table for selecting rows or modifying rows must be allowed by a row security policy. (However, the table's owner is typically not subject to row security policies.) If no policy exists for the table, a default-deny policy is used, meaning that no rows are visible or can be modified. Operations that apply to the whole table, such as TRUNCATE and REFERENCES, are not subject to row security.

Row security policies can be specific to commands, or to roles, or to both. A policy can be specified to apply to ALL commands, or to SELECT, INSERT, UPDATE, or DELETE. Multiple roles can be assigned to a given policy, and normal role membership and inheritance rules apply.

To specify which rows are visible or modifiable according to a policy, an expression is required that returns a Boolean result. This expression will be evaluated for each row prior to any conditions or functions coming from the user's query. (The only exceptions to this rule are leakproof functions, which are guaranteed to not leak information; the optimizer may choose to apply such functions ahead of the row-security check.) Rows for which the expression does not return true will not be processed. Separate expressions may be specified to provide independent control over the rows which are visible and the rows which are allowed to be modified. Policy expressions are run as part of the query and with the privileges of the user running the query, although security-definer functions can be used to access data not available to the calling user.

Superusers and roles with the BYPASSRLS attribute always bypass the row security system when accessing a table. Table owners normally bypass row security as well, though a table owner can choose to be subject to row security with ALTER TABLE ... FORCE ROW LEVEL SECURITY.

60
Enabling and disabling row security, as well as adding policies to a table, is always the privilege of the table owner only.

Policies are created using the CREATE POLICY command, altered using the ALTER POLICY command, and dropped using the DROP POLICY command. To enable and disable row security for a given table, use the ALTER TABLE command.

Each policy has a name and multiple policies can be defined for a table. As policies are table-specific, each policy for a table must have a unique name. Different tables may have policies with the same name.

When multiple policies apply to a given query, they are combined using either OR (for permissive policies, which are the default) or using AND (for restrictive policies). This is similar to the rule that a given role has the privileges of all roles that they are a member of. Permissive vs. restrictive policies are discussed further below.

As a simple example, here is how to create a policy on the account relation to allow only members of the managers role to access rows, and only rows of their accounts:

```sql
CREATE TABLE accounts (manager text, company text, contact_email text);
ALTER TABLE accounts ENABLE ROW LEVEL SECURITY;
CREATE POLICY account_managers ON accounts TO managers
   USING (manager = current_user);
```

The policy above implicitly provides a WITH CHECK clause identical to its USING clause, so that the constraint applies both to rows selected by a command (so a manager cannot SELECT, UPDATE, or DELETE existing rows belonging to a different manager) and to rows modified by a command (so rows belonging to a different manager cannot be created via INSERT or UPDATE).

If no role is specified, or the special user name PUBLIC is used, then the policy applies to all users on the system. To allow all users to access only their own row in a users table, a simple policy can be used:

```sql
CREATE POLICY user_policy ON users
   USING (user_name = current_user);
```

This works similarly to the previous example.

To use a different policy for rows that are being added to the table compared to those rows that are visible, multiple policies can be combined. This pair of policies would allow all users to view all rows in the users table, but only modify their own:

```sql
CREATE POLICY user_sel_policy ON users
   FOR SELECT
   USING (true);
CREATE POLICY user_mod_policy ON users
   USING (user_name = current_user);
```

In a SELECT command, these two policies are combined using OR, with the net effect being that all rows can be selected. In other command types, only the second policy applies, so that the effects are the same as before.

Row security can also be disabled with the ALTER TABLE command. Disabling row security does not remove any policies that are defined on the table; they are simply ignored. Then all rows in the table are visible and modifiable, subject to the standard SQL privileges system.

Below is a larger example of how this feature can be used in production environments. The table passwd emulates a Unix password file:

```sql
-- Simple passwd-file based example
```
### Data Definition

```sql
CREATE TABLE passwd (
    user_name             text UNIQUE NOT NULL,
    pwhash                text,
    uid                   int  PRIMARY KEY,
    gid                   int  NOT NULL,
    real_name             text NOT NULL,
    home_phone            text,
    extra_info            text,
    home_dir              text NOT NULL,
    shell                 text NOT NULL
);

CREATE ROLE admin;  -- Administrator
CREATE ROLE bob;    -- Normal user
CREATE ROLE alice;  -- Normal user

-- Populate the table
INSERT INTO passwd VALUES ('admin','xxx',0,0,'Admin','111-222-3333',null,'/root','/bin/dash');
INSERT INTO passwd VALUES ('bob','xxx',1,1,'Bob','123-456-7890',null,'/home/bob','/bin/zsh');
INSERT INTO passwd VALUES ('alice','xxx',2,1,'Alice','098-765-4321',null,'/home/alice','/bin/zsh');

-- Be sure to enable row-level security on the table
ALTER TABLE passwd ENABLE ROW LEVEL SECURITY;

-- Create policies
-- Administrator can see all rows and add any rows
CREATE POLICY admin_all ON passwd TO admin USING (true) WITH CHECK (true);
-- Normal users can view all rows
CREATE POLICY all_view ON passwd FOR SELECT USING (true);
-- Normal users can update their own records, but
-- limit which shells a normal user is allowed to set
CREATE POLICY user_mod ON passwd FOR UPDATE
    USING (current_user = user_name)
    WITH CHECK (current_user = user_name AND
                shell IN ('/bin/bash','/bin/sh','/bin/dash','/bin/zsh','/bin/tcsh'));

-- Allow admin all normal rights
GRANT SELECT, INSERT, UPDATE, DELETE ON passwd TO admin;
-- Users only get select access on public columns
GRANT SELECT
    (user_name, uid, gid, real_name, home_phone, extra_info, home_dir, shell)
ON passwd TO public;
-- Allow users to update certain columns
GRANT UPDATE
    (pwhash, real_name, home_phone, extra_info, shell)
ON passwd TO public;

As with any security settings, it's important to test and ensure that the system is behaving as expected. Using the example above, this demonstrates that the permission system is working properly.

-- admin can view all rows and fields
postgres=> set role admin;
SET
postgres=> table passwd;
```

---

62
All of the policies constructed thus far have been permissive policies, meaning that when multiple policies are applied they are combined using the "OR" Boolean operator. While permissive policies can be constructed to only allow access to rows in the intended cases, it can be simpler to combine permissive policies with restrictive policies (which the records must pass and which are combined using the "AND" Boolean operator). Building on the example above, we add a restrictive policy to require the administrator to be connected over a local Unix socket to access the records of the \texttt{passwd} table:

\texttt{CREATE POLICY admin\_local\_only ON passwd AS RESTRICTIVE TO admin USING (pg\_catalog.inet\_client\_addr() IS NULL);}

We can then see that an administrator connecting over a network will not see any records, due to the restrictive policy:

\texttt{=> SELECT current\_user;}
\texttt{current\_user}
\texttt{admin}
Data Definition

(1 row)

=> select inet_client_addr();

inet_client_addr
------------------
127.0.0.1
(1 row)

=> TABLE passwd;

user_name | pwhash | uid | gid | real_name | home_phone | extra_info | home_dir |
shell
-----------+--------+-----+-----+-----------+------------+------------+----------
+-------
(0 rows)

=> UPDATE passwd set pwhash = NULL;
UPDATE 0

Referential integrity checks, such as unique or primary key constraints and foreign key references, always bypass row security to ensure that data integrity is maintained. Care must be taken when developing schemas and row level policies to avoid “covert channel” leaks of information through such referential integrity checks.

In some contexts it is important to be sure that row security is not being applied. For example, when taking a backup, it could be disastrous if row security silently caused some rows to be omitted from the backup. In such a situation, you can set the row_security configuration parameter to off. This does not in itself bypass row security; what it does is throw an error if any query's results would get filtered by a policy. The reason for the error can then be investigated and fixed.

In the examples above, the policy expressions consider only the current values in the row to be accessed or updated. This is the simplest and best-performing case; when possible, it's best to design row security applications to work this way. If it is necessary to consult other rows or other tables to make a policy decision, that can be accomplished using sub-SELECTs, or functions that contain SELECTs, in the policy expressions. Be aware however that such accesses can create race conditions that could allow information leakage if care is not taken. As an example, consider the following table design:

-- definition of privilege groups
CREATE TABLE groups (group_id int PRIMARY KEY,
    group_name text NOT NULL);

INSERT INTO groups VALUES
    (1, 'low'),
    (2, 'medium'),
    (5, 'high');

GRANT ALL ON groups TO alice; -- alice is the administrator
GRANT SELECT ON groups TO public;

-- definition of users' privilege levels
CREATE TABLE users (user_name text PRIMARY KEY,
    group_id int NOT NULL REFERENCES groups);

INSERT INTO users VALUES
    ('alice', 5),
    ('bob', 2),
    ('mallory', 2);

GRANT ALL ON users TO alice;
GRANT SELECT ON users TO public;
Data Definition

-- table holding the information to be protected
CREATE TABLE information (info text,
   group_id int NOT NULL REFERENCES groups);

INSERT INTO information VALUES
   ('barely secret', 1),
   ('slightly secret', 2),
   ('very secret', 5);

ALTER TABLE information ENABLE ROW LEVEL SECURITY;

-- a row should be visible to/updatable by users whose security group_id is
-- greater than or equal to the row's group_id
CREATE POLICY fp_s ON information FOR SELECT
   USING (group_id <= (SELECT group_id FROM users WHERE user_name = current_user));
CREATE POLICY fp_u ON information FOR UPDATE
   USING (group_id <= (SELECT group_id FROM users WHERE user_name = current_user));

-- we rely only on RLS to protect the information table
GRANT ALL ON information TO public;

Now suppose that alice wishes to change the "slightly secret" information, but decides that mallory
should not be trusted with the new content of that row, so she does:

BEGIN;
UPDATE users SET group_id = 1 WHERE user_name = 'mallory';
UPDATE information SET info = 'secret from mallory' WHERE group_id = 2;
COMMIT;

That looks safe; there is no window wherein mallory should be able to see the "secret from mallory"
string. However, there is a race condition here. If mallory is concurrently doing, say,

SELECT * FROM information WHERE group_id = 2 FOR UPDATE;

and her transaction is in READ COMMITTED mode, it is possible for her to see "secret from mallory". That
happens if her transaction reaches the information row just after alice's does. It blocks waiting for
alice's transaction to commit, then fetches the updated row contents thanks to the FOR UPDATE clause.
However, it does not fetch an updated row for the implicit SELECT from users, because that sub-SELECT
did not have FOR UPDATE; instead the users row is read with the snapshot taken at the start of the query.
Therefore, the policy expression tests the old value of mallory's privilege level and allows her to see
the updated row.

There are several ways around this problem. One simple answer is to use SELECT ... FOR SHARE in
sub-SELECTs in row security policies. However, that requires granting UPDATE privilege on the referenced
table (here users) to the affected users, which might be undesirable. (But another row security policy
could be applied to prevent them from actually exercising that privilege; or the sub-SELECT could be
embedded into a security definer function.) Also, heavy concurrent use of row share locks on the
referenced table could pose a performance problem, especially if updates of it are frequent. Another
solution, practical if updates of the referenced table are infrequent, is to take an ACCESS EXCLUSIVE lock
on the referenced table when updating it, so that no concurrent transactions could be examining old
row values. Or one could just wait for all concurrent transactions to end after committing an update of
the referenced table and before making changes that rely on the new security situation.

For additional details see CREATE POLICY and ALTER TABLE.

5.9. Schemas

A Postgres Pro database cluster contains one or more named databases. Roles and a few other object
types are shared across the entire cluster. A client connection to the server can only access data in a
single database, the one specified in the connection request.
A database contains one or more named schemas, which in turn contain tables. Schemas also contain other kinds of named objects, including data types, functions, and operators. The same object name can be used in different schemas without conflict; for example, both \texttt{schema1} and \texttt{myschema} can contain tables named \texttt{mytable}. Unlike databases, schemas are not rigidly separated: a user can access objects in any of the schemas in the database they are connected to, if they have privileges to do so.

There are several reasons why one might want to use schemas:

- To allow many users to use one database without interfering with each other.
- To organize database objects into logical groups to make them more manageable.
- Third-party applications can be put into separate schemas so they do not collide with the names of other objects.

Schemas are analogous to directories at the operating system level, except that schemas cannot be nested.

### 5.9.1. Creating a Schema

To create a schema, use the \texttt{CREATE SCHEMA} command. Give the schema a name of your choice. For example:

\begin{verbatim}
CREATE SCHEMA myschema;
\end{verbatim}

To create or access objects in a schema, write a \textit{qualified name} consisting of the schema name and table name separated by a dot:

\begin{verbatim}
schema.table
\end{verbatim}

This works anywhere a table name is expected, including the table modification commands and the data access commands discussed in the following chapters. (For brevity we will speak of tables only, but the same ideas apply to other kinds of named objects, such as types and functions.)

Actually, the even more general syntax

\begin{verbatim}
database.schema.table
\end{verbatim}

can be used too, but at present this is just for pro forma compliance with the SQL standard. If you write a database name, it must be the same as the database you are connected to.

So to create a table in the new schema, use:

\begin{verbatim}
CREATE TABLE myschema.mytable ( ...
);
\end{verbatim}

To drop a schema if it's empty (all objects in it have been dropped), use:

\begin{verbatim}
DROP SCHEMA myschema;
\end{verbatim}

To drop a schema including all contained objects, use:

\begin{verbatim}
DROP SCHEMA myschema CASCADE;
\end{verbatim}

See \textsection{5.14} for a description of the general mechanism behind this.
Often you will want to create a schema owned by someone else (since this is one of the ways to restrict
the activities of your users to well-defined namespaces). The syntax for that is:

```
CREATE SCHEMA schema_name AUTHORIZATION user_name;
```

You can even omit the schema name, in which case the schema name will be the same as the user name.
See Section 5.9.6 for how this can be useful.

Schema names beginning with `pg_` are reserved for system purposes and cannot be created by users.

### 5.9.2. The Public Schema

In the previous sections we created tables without specifying any schema names. By default such tables
(and other objects) are automatically put into a schema named “public”. Every new database contains
such a schema. Thus, the following are equivalent:

```
CREATE TABLE products ( ... );
```

and:

```
CREATE TABLE public.products ( ... );
```

### 5.9.3. The Schema Search Path

Qualified names are tedious to write, and it's often best not to wire a particular schema name into
applications anyway. Therefore tables are often referred to by unqualified names, which consist of just
the table name. The system determines which table is meant by following a search path, which is a list
of schemas to look in. The first matching table in the search path is taken to be the one wanted. If there
is no match in the search path, an error is reported, even if matching table names exist in other schemas
in the database.

The ability to create like-named objects in different schemas complicates writing a query that references
precisely the same objects every time. It also opens up the potential for users to change the behavior of
other users' queries, maliciously or accidentally. Due to the prevalence of unqualified names in queries
and their use in Postgres Pro internals, adding a schema to `search_path` effectively trusts all users
having `CREATE` privilege on that schema. When you run an ordinary query, a malicious user able to create
objects in a schema of your search path can take control and execute arbitrary SQL functions as though
you executed them.

The first schema named in the search path is called the current schema. Aside from being the first
schema searched, it is also the schema in which new tables will be created if the `CREATE TABLE`
command does not specify a schema name.

To show the current search path, use the following command:

```
SHOW search_path;
```

In the default setup this returns:

```
search_path
----------
"$user", public
```

The first element specifies that a schema with the same name as the current user is to be searched. If
no such schema exists, the entry is ignored. The second element refers to the public schema that we
have seen already.

The first schema in the search path that exists is the default location for creating new objects. That is
the reason that by default objects are created in the public schema. When objects are referenced in any
other context without schema qualification (table modification, data modification, or query commands)
the search path is traversed until a matching object is found. Therefore, in the default configuration,
any unqualified access again can only refer to the public schema.
To put our new schema in the path, we use:

```
SET search_path TO myschema,public;
```

(We omit the $user here because we have no immediate need for it.) And then we can access the table without schema qualification:

```
DROP TABLE mytable;
```

Also, since `myschema` is the first element in the path, new objects would by default be created in it.

We could also have written:

```
SET search_path TO myschema;
```

Then we no longer have access to the public schema without explicit qualification. There is nothing special about the public schema except that it exists by default. It can be dropped, too.

See also Section 9.26 for other ways to manipulate the schema search path.

The search path works in the same way for data type names, function names, and operator names as it does for table names. Data type and function names can be qualified in exactly the same way as table names. If you need to write a qualified operator name in an expression, there is a special provision: you must write

```
OPERATOR(schema.operator)
```

This is needed to avoid syntactic ambiguity. An example is:

```
SELECT 3 OPERATOR(pg_catalog.+ 4;
```

In practice one usually relies on the search path for operators, so as not to have to write anything so ugly as that.

### 5.9.4. Schemas and Privileges

By default, users cannot access any objects in schemas they do not own. To allow that, the owner of the schema must grant the `USAGE` privilege on the schema. To allow users to make use of the objects in the schema, additional privileges might need to be granted, as appropriate for the object.

A user can also be allowed to create objects in someone else's schema. To allow that, the `CREATE` privilege on the schema needs to be granted. Note that by default, everyone has `CREATE` and `USAGE` privileges on the schema `public`. This allows all users that are able to connect to a given database to create objects in its `public` schema. Some usage patterns call for revoking that privilege:

```
REVOKE CREATE ON SCHEMA public FROM PUBLIC;
```

(The first “public” is the schema, the second “public” means “every user”. In the first sense it is an identifier, in the second sense it is a key word, hence the different capitalization; recall the guidelines from Section 4.1.1.)

### 5.9.5. The System Catalog Schema

In addition to `public` and user-created schemas, each database contains a `pg_catalog` schema, which contains the system tables and all the built-in data types, functions, and operators. `pg_catalog` is always effectively part of the search path. If it is not named explicitly in the path then it is implicitly searched before searching the path's schemas. This ensures that built-in names will always be findable. However, you can explicitly place `pg_catalog` at the end of your search path if you prefer to have user-defined names override built-in names.

Since system table names begin with `pg_`, it is best to avoid such names to ensure that you won't suffer a conflict if some future version defines a system table named the same as your table. (With the default search path, an unqualified reference to your table name would then be resolved as the system table instead.) System tables will continue to follow the convention of having names beginning with `pg_`, so that they will not conflict with unqualified user-table names so long as users avoid the `pg_` prefix.
5.9.6. Usage Patterns

Schemas can be used to organize your data in many ways. A secure schema usage pattern prevents untrusted users from changing the behavior of other users' queries. When a database does not use a secure schema usage pattern, users wishing to securely query that database would take protective action at the beginning of each session. Specifically, they would begin each session by setting search_path to the empty string or otherwise removing non-superuser-writable schemas from search_path. There are a few usage patterns easily supported by the default configuration:

- **Constrain ordinary users to user-private schemas.** To implement this, issue `REVOKE CREATE ON SCHEMA public FROM PUBLIC`, and create a schema for each user with the same name as that user. Recall that the default search path starts with $user, which resolves to the user name. Therefore, if each user has a separate schema, they access their own schemas by default. After adopting this pattern in a database where untrusted users had already logged in, consider auditing the public schema for objects named like objects in schema `pg_catalog`. This pattern is a secure schema usage pattern unless an untrusted user is the database owner or holds the `CREATEROLE` privilege, in which case no secure schema usage pattern exists.

- **Remove the public schema from the default search path,** by modifying `postgresql.conf` or by issuing `ALTER ROLE ALL SET search_path = "$user"`. Everyone retains the ability to create objects in the public schema, but only qualified names will choose those objects. While qualified table references are fine, calls to functions in the public schema will be unsafe or unreliable. If you create functions or extensions in the public schema, use the first pattern instead. Otherwise, like the first pattern, this is secure unless an untrusted user is the database owner or holds the `CREATEROLE` privilege.

- **Keep the default.** All users access the public schema implicitly. This simulates the situation where schemas are not available at all, giving a smooth transition from the non-schema-aware world. However, this is never a secure pattern. It is acceptable only when the database has a single user or a few mutually-trusting users.

For any pattern, to install shared applications (tables to be used by everyone, additional functions provided by third parties, etc.), put them into separate schemas. Remember to grant appropriate privileges to allow the other users to access them. Users can then refer to these additional objects by qualifying the names with a schema name, or they can put the additional schemas into their search path, as they choose.

5.9.7. Portability

In the SQL standard, the notion of objects in the same schema being owned by different users does not exist. Moreover, some implementations do not allow you to create schemas that have a different name than their owner. In fact, the concepts of schema and user are nearly equivalent in a database system that implements only the basic schema support specified in the standard. Therefore, many users consider qualified names to really consist of `user_name.table_name`. This is how Postgres Pro will effectively behave if you create a per-user schema for every user.

Also, there is no concept of a public schema in the SQL standard. For maximum conformance to the standard, you should not use the public schema.

Of course, some SQL database systems might not implement schemas at all, or provide namespace support by allowing (possibly limited) cross-database access. If you need to work with those systems, then maximum portability would be achieved by not using schemas at all.

5.10. Inheritance

Postgres Pro implements table inheritance, which can be a useful tool for database designers. (SQL:1999 and later define a type inheritance feature, which differs in many respects from the features described here.)
Let's start with an example: suppose we are trying to build a data model for cities. Each state has many cities, but only one capital. We want to be able to quickly retrieve the capital city for any particular state. This can be done by creating two tables, one for state capitals and one for cities that are not capitals. However, what happens when we want to ask for data about a city, regardless of whether it is a capital or not? The inheritance feature can help to resolve this problem. We define the \textit{capitals} table so that it inherits from \textit{cities}:

\begin{verbatim}
CREATE TABLE cities (  
  name text,  
  population float,  
  elevation int     -- in feet
);

CREATE TABLE capitals (  
  state char(2)  
) INHERITS (cities);
\end{verbatim}

In this case, the \textit{capitals} table \textit{inherits} all the columns of its parent table, \textit{cities}. State capitals also have an extra column, \textit{state}, that shows their state.

In Postgres Pro, a table can inherit from zero or more other tables, and a query can reference either all rows of a table or all rows of a table plus all of its descendant tables. The latter behavior is the default. For example, the following query finds the names of all cities, including state capitals, that are located at an elevation over 500 feet:

\begin{verbatim}
SELECT name, elevation  
FROM cities  
WHERE elevation > 500;
\end{verbatim}

Given the sample data from the Postgres Pro tutorial (see Section 2.1), this returns:

<table>
<thead>
<tr>
<th>name</th>
<th>elevation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Las Vegas</td>
<td>2174</td>
</tr>
<tr>
<td>Mariposa</td>
<td>1953</td>
</tr>
<tr>
<td>Madison</td>
<td>845</td>
</tr>
</tbody>
</table>

On the other hand, the following query finds all the cities that are not state capitals and are situated at an elevation over 500 feet:

\begin{verbatim}
SELECT name, elevation  
FROM ONLY cities  
WHERE elevation > 500;
\end{verbatim}

\begin{verbatim}
<table>
<thead>
<tr>
<th>name</th>
<th>elevation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Las Vegas</td>
<td>2174</td>
</tr>
<tr>
<td>Mariposa</td>
<td>1953</td>
</tr>
</tbody>
</table>
\end{verbatim}

Here the \textit{ONLY} keyword indicates that the query should apply only to \textit{cities}, and not any tables below \textit{cities} in the inheritance hierarchy. Many of the commands that we have already discussed — \textit{SELECT}, \textit{UPDATE} and \textit{DELETE} — support the \textit{ONLY} keyword.

You can also write the table name with a trailing \textit{*} to explicitly specify that descendant tables are included:

\begin{verbatim}
SELECT name, elevation  
FROM cities*  
WHERE elevation > 500;
\end{verbatim}

Writing \textit{*} is not necessary, since this behavior is always the default. However, this syntax is still supported for compatibility with older releases where the default could be changed.
In some cases you might wish to know which table a particular row originated from. There is a system column called `tableoid` in each table which can tell you the originating table:

```
SELECT c.tableoid, c.name, c.elevation
FROM cities c
WHERE c.elevation > 500;
```

which returns:

<table>
<thead>
<tr>
<th>tableoid</th>
<th>name</th>
<th>elevation</th>
</tr>
</thead>
<tbody>
<tr>
<td>139793</td>
<td>Las Vegas</td>
<td>2174</td>
</tr>
<tr>
<td>139793</td>
<td>Mariposa</td>
<td>1953</td>
</tr>
<tr>
<td>139798</td>
<td>Madison</td>
<td>845</td>
</tr>
</tbody>
</table>

(If you try to reproduce this example, you will probably get different numeric OIDs.) By doing a join with `pg_class` you can see the actual table names:

```
SELECT p.relname, c.name, c.elevation
FROM cities c, pg_class p
WHERE c.elevation > 500 AND c.tableoid = p.oid;
```

which returns:

<table>
<thead>
<tr>
<th>relname</th>
<th>name</th>
<th>elevation</th>
</tr>
</thead>
<tbody>
<tr>
<td>cities</td>
<td>Las Vegas</td>
<td>2174</td>
</tr>
<tr>
<td>cities</td>
<td>Mariposa</td>
<td>1953</td>
</tr>
<tr>
<td>capitals</td>
<td>Madison</td>
<td>845</td>
</tr>
</tbody>
</table>

Another way to get the same effect is to use the `regclass` alias type, which will print the table OID symbolically:

```
SELECT c.tableoid::regclass, c.name, c.elevation
FROM cities c
WHERE c.elevation > 500;
```

Inheritance does not automatically propagate data from `INSERT` or `COPY` commands to other tables in the inheritance hierarchy. In our example, the following `INSERT` statement will fail:

```
INSERT INTO cities (name, population, elevation, state)
VALUES ('Albany', NULL, NULL, 'NY');
```

We might hope that the data would somehow be routed to the `capitals` table, but this does not happen: `INSERT` always inserts into exactly the table specified. In some cases it is possible to redirect the insertion using a rule (see Chapter 39). However that does not help for the above case because the `cities` table does not contain the column `state`, and so the command will be rejected before the rule can be applied.

All check constraints and not-null constraints on a parent table are automatically inherited by its children, unless explicitly specified otherwise with `NO INHERIT` clauses. Other types of constraints (unique, primary key, and foreign key constraints) are not inherited.

A table can inherit from more than one parent table, in which case it has the union of the columns defined by the parent tables. Any columns declared in the child table’s definition are added to these. If the same column name appears in multiple parent tables, or in both a parent table and the child’s definition, then these columns are “merged” so that there is only one such column in the child table. To be merged, columns must have the same data types, else an error is raised. Inheritable check constraints and not-null constraints are merged in a similar fashion. Thus, for example, a merged column will be marked not-null if any one of the column definitions it came from is marked not-null. Check constraints are merged if they have the same name, and the merge will fail if their conditions are different.

Table inheritance is typically established when the child table is created, using the `INHERITS` clause of the `CREATE TABLE` statement. Alternatively, a table which is already defined in a compatible way
can have a new parent relationship added, using the INHERIT variant of ALTER TABLE. To do this the new child table must already include columns with the same names and types as the columns of the parent. Similarly an inheritance link can be removed from a child using the NO INHERIT variant of ALTER TABLE. Dynamically adding and removing inheritance links like this can be useful when the inheritance relationship is being used for table partitioning (see Section 5.11).

One convenient way to create a compatible table that will later be made a new child is to use the LIKE clause in CREATE TABLE. This creates a new table with the same columns as the source table. If there are any CHECK constraints defined on the source table, the INCLUDING CONSTRAINTS option to LIKE should be specified, as the new child must have constraints matching the parent to be considered compatible.

A parent table cannot be dropped while any of its children remain. Neither can columns or check constraints of child tables be dropped or altered if they are inherited from any parent tables. If you wish to remove a table and all of its descendants, one easy way is to drop the parent table with the CASCADE option (see Section 5.14).

ALTER TABLE will propagate any changes in column data definitions and check constraints down the inheritance hierarchy. Again, dropping columns that are depended on by other tables is only possible when using the CASCADE option. ALTER TABLE follows the same rules for duplicate column merging and rejection that apply during CREATE TABLE.

Inherited queries perform access permission checks on the parent table only. Thus, for example, granting UPDATE permission on the cities table implies permission to update rows in the capitals table as well, when they are accessed through cities. This preserves the appearance that the data is (also) in the parent table. But the capitals table could not be updated directly without an additional grant. In a similar way, the parent table's row security policies (see Section 5.8) are applied to rows coming from child tables during an inherited query. A child table’s policies, if any, are applied only when it is the table explicitly named in the query; and in that case, any policies attached to its parent(s) are ignored.

Foreign tables (see Section 5.12) can also be part of inheritance hierarchies, either as parent or child tables, just as regular tables can be. If a foreign table is part of an inheritance hierarchy then any operations not supported by the foreign table are not supported on the whole hierarchy either.

5.10.1. Caveats

Note that not all SQL commands are able to work on inheritance hierarchies. Commands that are used for data querying, data modification, or schema modification (e.g., SELECT, UPDATE, DELETE, most variants of ALTER TABLE, but not INSERT or ALTER TABLE ... RENAME) typically default to including child tables and support the ONLY notation to exclude them. Commands that do database maintenance and tuning (e.g., REINDEX, VACUUM) typically only work on individual, physical tables and do not support recursing over inheritance hierarchies. The respective behavior of each individual command is documented in its reference page (SQL Commands).

A serious limitation of the inheritance feature is that indexes (including unique constraints) and foreign key constraints only apply to single tables, not to their inheritance children. This is true on both the referencing and referenced sides of a foreign key constraint. Thus, in the terms of the above example:

- If we declared cities.name to be UNIQUE or a PRIMARY KEY, this would not stop the capitals table from having rows with names duplicating rows in cities. And those duplicate rows would by default show up in queries from cities. In fact, by default capitals would have no unique constraint at all, and so could contain multiple rows with the same name. You could add a unique constraint to capitals, but this would not prevent duplication compared to cities.

- Similarly, if we were to specify that cities.name REFERENCES some other table, this constraint would not automatically propagate to capitals. In this case you could work around it by manually adding the same REFERENCES constraint to capitals.

- Specifying that another table's column REFERENCES cities(name) would allow the other table to contain city names, but not capital names. There is no good workaround for this case.
Some functionality not implemented for inheritance hierarchies is implemented for declarative partitioning. Considerable care is needed in deciding whether partitioning with legacy inheritance is useful for your application.

5.11. Table Partitioning

Postgres Pro supports basic table partitioning. This section describes why and how to implement partitioning as part of your database design.

5.11.1. Overview

Partitioning refers to splitting what is logically one large table into smaller physical pieces. Partitioning can provide several benefits:

• Query performance can be improved dramatically in certain situations, particularly when most of the heavily accessed rows of the table are in a single partition or a small number of partitions. Partitioning effectively substitutes for the upper tree levels of indexes, making it more likely that the heavily-used parts of the indexes fit in memory.

• When queries or updates access a large percentage of a single partition, performance can be improved by using a sequential scan of that partition instead of using an index, which would require random-access reads scattered across the whole table.

• Bulk loads and deletes can be accomplished by adding or removing partitions, if the usage pattern is accounted for in the partitioning design. Dropping an individual partition using DROP TABLE, or doing ALTER TABLE DETACH PARTITION, is far faster than a bulk operation. These commands also entirely avoid the VACUUM overhead caused by a bulk DELETE.

• Seldom-used data can be migrated to cheaper and slower storage media.

These benefits will normally be worthwhile only when a table would otherwise be very large. The exact point at which a table will benefit from partitioning depends on the application, although a rule of thumb is that the size of the table should exceed the physical memory of the database server.

Postgres Pro offers built-in support for the following forms of partitioning:

Range Partitioning

The table is partitioned into “ranges” defined by a key column or set of columns, with no overlap between the ranges of values assigned to different partitions. For example, one might partition by date ranges, or by ranges of identifiers for particular business objects. Each range's bounds are understood as being inclusive at the lower end and exclusive at the upper end. For example, if one partition's range is from \(1\) to \(10\), and the next one's range is from \(10\) to \(20\), then value \(10\) belongs to the second partition not the first.

List Partitioning

The table is partitioned by explicitly listing which key value(s) appear in each partition.

Hash Partitioning

The table is partitioned by specifying a modulus and a remainder for each partition. Each partition will hold the rows for which the hash value of the partition key divided by the specified modulus will produce the specified remainder.

If your application needs to use other forms of partitioning not listed above, alternative methods such as inheritance and UNION ALL views can be used instead. Such methods offer flexibility but do not have some of the performance benefits of built-in declarative partitioning.

5.11.2. Declarative Partitioning

Postgres Pro allows you to declare that a table is divided into partitions. The table that is divided is referred to as a partitioned table. The declaration includes the partitioning method as described above, plus a list of columns or expressions to be used as the partition key.
The partitioned table itself is a “virtual” table having no storage of its own. Instead, the storage belongs to partitions, which are otherwise-ordinary tables associated with the partitioned table. Each partition stores a subset of the data as defined by its partition bounds. All rows inserted into a partitioned table will be routed to the appropriate one of the partitions based on the values of the partition key column(s). Updating the partition key of a row will cause it to be moved into a different partition if it no longer satisfies the partition bounds of its original partition.

Partitions may themselves be defined as partitioned tables, resulting in sub-partitioning. Although all partitions must have the same columns as their partitioned parent, partitions may have their own indexes, constraints and default values, distinct from those of other partitions. See CREATE TABLE for more details on creating partitioned tables and partitions.

It is not possible to turn a regular table into a partitioned table or vice versa. However, it is possible to add an existing regular or partitioned table as a partition of a partitioned table, or remove a partition from a partitioned table turning it into a standalone table; this can simplify and speed up many maintenance processes. See ALTER TABLE to learn more about the ATTACH PARTITION and DETACH PARTITION sub-commands.

Partitions can also be foreign tables, although they have some limitations that normal tables do not; see CREATE FOREIGN TABLE for more information.

5.11.2.1. Example

Suppose we are constructing a database for a large ice cream company. The company measures peak temperatures every day as well as ice cream sales in each region. Conceptually, we want a table like:

```sql
CREATE TABLE measurement (
    city_id int not null,
    logdate date not null,
    peaktemp int,
    unitsales int
);
```

We know that most queries will access just the last week's, month's or quarter's data, since the main use of this table will be to prepare online reports for management. To reduce the amount of old data that needs to be stored, we decide to keep only the most recent 3 years worth of data. At the beginning of each month we will remove the oldest month's data. In this situation we can use partitioning to help us meet all of our different requirements for the measurements table.

To use declarative partitioning in this case, use the following steps:

1. Create the measurement table as a partitioned table by specifying the PARTITION BY clause, which includes the partitioning method (RANGE in this case) and the list of column(s) to use as the partition key.

```sql
CREATE TABLE measurement (
    city_id int not null,
    logdate date not null,
    peaktemp int,
    unitsales int
) PARTITION BY RANGE (logdate);
```

2. Create partitions. Each partition's definition must specify bounds that correspond to the partitioning method and partition key of the parent. Note that specifying bounds such that the new partition's values would overlap with those in one or more existing partitions will cause an error.

Partitions thus created are in every way normal Postgres Pro tables (or, possibly, foreign tables). It is possible to specify a tablespace and storage parameters for each partition separately.

For our example, each partition should hold one month's worth of data, to match the requirement of deleting one month's data at a time. So the commands might look like:

```sql
CREATE TABLE measurement_y2006m02 PARTITION OF measurement
```
FOR VALUES FROM ('2006-02-01') TO ('2006-03-01');

CREATE TABLE measurement_y2006m03 PARTITION OF measurement
FOR VALUES FROM ('2006-03-01') TO ('2006-04-01');

...  

CREATE TABLE measurement_y2006m02 PARTITION OF measurement
FOR VALUES FROM ('2006-02-01') TO ('2006-03-01')
PARTITION BY RANGE (peaktemp);

After creating partitions of measurement_y2006m02, any data inserted into measurement
that is mapped to measurement_y2006m02 (or data that is directly inserted into measurement_y2006m02,
which is allowed provided its partition constraint is satisfied) will be further redirected to one of its
partitions based on the peaktemp column. The partition key specified may overlap with the parent's
partition key, although care should be taken when specifying the bounds of a sub-partition such that
the set of data it accepts constitutes a subset of what the partition's own bounds allow; the system
does not try to check whether that's really the case.

Inserting data into the parent table that does not map to one of the existing partitions will cause an
error; an appropriate partition must be added manually.

It is not necessary to manually create table constraints describing the partition boundary conditions
for partitions. Such constraints will be created automatically.

3. Create an index on the key column(s), as well as any other indexes you might want, on the partitioned
table. (The key index is not strictly necessary, but in most scenarios it is helpful.) This automatically
creates a matching index on each partition, and any partitions you create or attach later will also have
such an index. An index or unique constraint declared on a partitioned table is “virtual” in the same
way that the partitioned table is: the actual data is in child indexes on the individual partition tables.

CREATE INDEX ON measurement (logdate);

4. Ensure that the enable_partition_pruning configuration parameter is not disabled in
postgresql.conf. If it is, queries will not be optimized as desired.

In the above example we would be creating a new partition each month, so it might be wise to write a
script that generates the required DDL automatically.

5.11.2.2. Partition Maintenance

Normally the set of partitions established when initially defining the table is not intended to remain
static. It is common to want to remove partitions holding old data and periodically add new partitions for
new data. One of the most important advantages of partitioning is precisely that it allows this otherwise
painful task to be executed nearly instantaneously by manipulating the partition structure, rather than
physically moving large amounts of data around.
The simplest option for removing old data is to drop the partition that is no longer necessary:

DROP TABLE measurement_y2006m02;

This can very quickly delete millions of records because it doesn't have to individually delete every record. Note however that the above command requires taking an `ACCESS EXCLUSIVE` lock on the parent table.

Another option that is often preferable is to remove the partition from the partitioned table but retain access to it as a table in its own right. This has two forms:

ALTER TABLE measurement DETACH PARTITION measurement_y2006m02;
ALTER TABLE measurement DETACH PARTITION measurement_y2006m02 CONCURRENTLY;

These allow further operations to be performed on the data before it is dropped. For example, this is often a useful time to back up the data using `COPY`, `pg_dump`, or similar tools. It might also be a useful time to aggregate data into smaller formats, perform other data manipulations, or run reports. The first form of the command requires an `ACCESS EXCLUSIVE` lock on the parent table. Adding the `CONCURRENTLY` qualifier as in the second form allows the detach operation to require only `SHARE UPDATE EXCLUSIVE` lock on the parent table, but see `ALTER TABLE ... DETACH PARTITION` for details on the restrictions.

Similarly we can add a new partition to handle new data. We can create an empty partition in the partitioned table just as the original partitions were created above:

CREATE TABLE measurement_y2008m02 PARTITION OF measurement
    FOR VALUES FROM ('2008-02-01') TO ('2008-03-01')
    TABLESPACE fasttablespace;

As an alternative, it is sometimes more convenient to create the new table outside the partition structure, and make it a proper partition later. This allows new data to be loaded, checked, and transformed prior to it appearing in the partitioned table. The `CREATE TABLE ... LIKE` option is helpful to avoid tediously repeating the parent table's definition:

CREATE TABLE measurement_y2008m02
    (LIKE measurement INCLUDING DEFAULTS INCLUDING CONSTRAINTS)
    TABLESPACE fasttablespace;

ALTER TABLE measurement_y2008m02 ADD CONSTRAINT y2008m02
    CHECK ( logdate >= DATE '2008-02-01' AND logdate < DATE '2008-03-01' );

\copy measurement_y2008m02 from 'measurement_y2008m02'
   -- possibly some other data preparation work

ALTER TABLE measurement ATTACH PARTITION measurement_y2008m02
    FOR VALUES FROM ('2008-02-01') TO ('2008-03-01');

The `ATTACH PARTITION` command requires taking a `SHARE UPDATE EXCLUSIVE` lock on the partitioned table.

Before running the `ATTACH PARTITION` command, it is recommended to create a `CHECK` constraint on the table to be attached that matches the expected partition constraint, as illustrated above. That way, the system will be able to skip the scan which is otherwise needed to validate the implicit partition constraint. Without the `CHECK` constraint, the table will be scanned to validate the partition constraint while holding an `ACCESS EXCLUSIVE` lock on that partition. It is recommended to drop the now-redundant `CHECK` constraint after the `ATTACH PARTITION` is complete. If the table being attached is itself a partitioned table then each of its sub-partitions will be recursively locked and scanned until either a suitable `CHECK` constraint is encountered or the leaf partitions are reached.

Similarly, if the partitioned table has a `DEFAULT` partition, it is recommended to create a `CHECK` constraint which excludes the to-be-attached partition's constraint. If this is not done then the `DEFAULT` partition will be scanned to verify that it contains no records which should be located in the partition being attached.
This operation will be performed whilst holding an **ACCESS EXCLUSIVE** lock on the **DEFAULT** partition. If the **DEFAULT** partition is itself a partitioned table then each of its partitions will be recursively checked in the same way as the table being attached, as mentioned above.

As explained above, it is possible to create indexes on partitioned tables so that they are applied automatically to the entire hierarchy. This is very convenient, as not only will the existing partitions become indexed, but also any partitions that are created in the future will. One limitation is that it's not possible to use the **CONCURRENTLY** qualifier when creating such a partitioned index. To avoid long lock times, it is possible to use **CREATE INDEX ON ONLY** the partitioned table; such an index is marked invalid, and the partitions do not get the index applied automatically. The indexes on partitions can be created individually using **CONCURRENTLY**, and then **ATTACH PARTITION**. Once indexes for all partitions are attached to the parent index, the parent index is marked valid automatically. Example:

```sql
CREATE INDEX measurement_usls_idx ON ONLY measurement (unitsales);

CREATE INDEX measurement_usls_200602_idx
    ON measurement_y2006m02 (unitsales);

ALTER INDEX measurement_usls_idx
    ATTACH PARTITION measurement_usls_200602_idx;
```

This technique can be used with **UNIQUE** and **PRIMARY KEY** constraints too; the indexes are created implicitly when the constraint is created. Example:

```sql
ALTER TABLE ONLY measurement ADD UNIQUE (city_id, logdate);

ALTER TABLE measurement_y2006m02 ADD UNIQUE (city_id, logdate);

ALTER INDEX measurement_city_id_logdate_key
    ATTACH PARTITION measurement_y2006m02_city_id_logdate_key;
```

### 5.11.2.3. Limitations

The following limitations apply to partitioned tables:

- Unique constraints (and hence primary keys) on partitioned tables must include all the partition key columns. This limitation exists because the individual indexes making up the constraint can only directly enforce uniqueness within their own partitions; therefore, the partition structure itself must guarantee that there are not duplicates in different partitions.

- There is no way to create an exclusion constraint spanning the whole partitioned table. It is only possible to put such a constraint on each leaf partition individually. Again, this limitation stems from not being able to enforce cross-partition restrictions.

- **BEFORE ROW** triggers on **INSERT** cannot change which partition is the final destination for a new row.

- Mixing temporary and permanent relations in the same partition tree is not allowed. Hence, if the partitioned table is permanent, so must be its partitions and likewise if the partitioned table is temporary. When using temporary relations, all members of the partition tree have to be from the same session.

Individual partitions are linked to their partitioned table using inheritance behind-the-scenes. However, it is not possible to use all of the generic features of inheritance with declaratively partitioned tables or their partitions, as discussed below. Notably, a partition cannot have any parents other than the partitioned table it is a partition of, nor can a table inherit from both a partitioned table and a regular table. That means partitioned tables and their partitions never share an inheritance hierarchy with regular tables.

Since a partition hierarchy consisting of the partitioned table and its partitions is still an inheritance hierarchy, **tableoid** and all the normal rules of inheritance apply as described in Section 5.10, with a few exceptions:
• Partitions cannot have columns that are not present in the parent. It is not possible to specify columns when creating partitions with `CREATE TABLE`, nor is it possible to add columns to partitions after-the-fact using `ALTER TABLE`. Tables may be added as a partition with `ALTER TABLE ... ATTACH PARTITION` only if their columns exactly match the parent.

• Both `CHECK` and `NOT NULL` constraints of a partitioned table are always inherited by all its partitions. `CHECK` constraints that are marked `NO INHERIT` are not allowed to be created on partitioned tables. You cannot drop a `NOT NULL` constraint on a partition's column if the same constraint is present in the parent table.

• Using `ONLY` to add or drop a constraint on only the partitioned table is supported as long as there are no partitions. Once partitions exist, using `ONLY` will result in an error. Instead, constraints on the partitions themselves can be added and (if they are not present in the parent table) dropped.

• As a partitioned table does not have any data itself, attempts to use `TRUNCATE ONLY` on a partitioned table will always return an error.

5.11.3. Partitioning Using Inheritance

While the built-in declarative partitioning is suitable for most common use cases, there are some circumstances where a more flexible approach may be useful. Partitioning can be implemented using table inheritance, which allows for several features not supported by declarative partitioning, such as:

• For declarative partitioning, partitions must have exactly the same set of columns as the partitioned table, whereas with table inheritance, child tables may have extra columns not present in the parent.

• Table inheritance allows for multiple inheritance.

• Declarative partitioning only supports range, list and hash partitioning, whereas table inheritance allows data to be divided in a manner of the user's choosing. (Note, however, that if constraint exclusion is unable to prune child tables effectively, query performance might be poor.)

5.11.3.1. Example

This example builds a partitioning structure equivalent to the declarative partitioning example above. Use the following steps:

1. Create the “root” table, from which all of the “child” tables will inherit. This table will contain no data. Do not define any check constraints on this table, unless you intend them to be applied equally to all child tables. There is no point in defining any indexes or unique constraints on it, either. For our example, the root table is the `measurement` table as originally defined:

   ```sql
   CREATE TABLE measurement (  
     city_id         int not null,  
     logdate         date not null,  
     peaktemp        int,  
     unitsales       int  
   );
   ```

2. Create several “child” tables that each inherit from the root table. Normally, these tables will not add any columns to the set inherited from the root. Just as with declarative partitioning, these tables are in every way normal Postgres Pro tables (or foreign tables).

   ```sql
   CREATE TABLE measurement_y2006m02 () INHERITS (measurement);  
   CREATE TABLE measurement_y2006m03 () INHERITS (measurement);  
   ...  
   CREATE TABLE measurement_y2007m11 () INHERITS (measurement);  
   CREATE TABLE measurement_y2007m12 () INHERITS (measurement);  
   CREATE TABLE measurement_y2008m01 () INHERITS (measurement);  
   ```

3. Add non-overlapping table constraints to the child tables to define the allowed key values in each.

   Typical examples would be:

   ```sql
   CHECK ( x = 1 )
   ```
CHECK ( county IN ( 'Oxfordshire', 'Buckinghamshire', 'Warwickshire' ))
CHECK ( outletID >= 100 AND outletID < 200 )

Ensure that the constraints guarantee that there is no overlap between the key values permitted in different child tables. A common mistake is to set up range constraints like:

CHECK ( outletID BETWEEN 100 AND 200 )
CHECK ( outletID BETWEEN 200 AND 300 )

This is wrong since it is not clear which child table the key value 200 belongs in. Instead, ranges should be defined in this style:

CREATE TABLE measurement_y2006m02 (  
    CHECK ( logdate >= DATE '2006-02-01' AND logdate < DATE '2006-03-01' )  
) INHERITS (measurement);

CREATE TABLE measurement_y2006m03 (  
    CHECK ( logdate >= DATE '2006-03-01' AND logdate < DATE '2006-04-01' )  
) INHERITS (measurement);

...  
CREATE TABLE measurement_y2007m11 (  
    CHECK ( logdate >= DATE '2007-11-01' AND logdate < DATE '2007-12-01' )  
) INHERITS (measurement);

CREATE TABLE measurement_y2007m12 (  
    CHECK ( logdate >= DATE '2007-12-01' AND logdate < DATE '2008-01-01' )  
) INHERITS (measurement);

CREATE TABLE measurement_y2008m01 (  
    CHECK ( logdate >= DATE '2008-01-01' AND logdate < DATE '2008-02-01' )  
) INHERITS (measurement);

4. For each child table, create an index on the key column(s), as well as any other indexes you might want.

CREATE INDEX measurement_y2006m02_logdate ON measurement_y2006m02 (logdate);
CREATE INDEX measurement_y2006m03_logdate ON measurement_y2006m03 (logdate);
CREATE INDEX measurement_y2007m11_logdate ON measurement_y2007m11 (logdate);
CREATE INDEX measurement_y2007m12_logdate ON measurement_y2007m12 (logdate);
CREATE INDEX measurement_y2008m01_logdate ON measurement_y2008m01 (logdate);

5. We want our application to be able to say INSERT INTO measurement ... and have the data be redirected into the appropriate child table. We can arrange that by attaching a suitable trigger function to the root table. If data will be added only to the latest child, we can use a very simple trigger function:

CREATE OR REPLACE FUNCTION measurement_insert_trigger()  
RETURNS TRIGGER AS $$
BEGIN
    INSERT INTO measurement_y2008m01 VALUES (NEW.*);
    RETURN NULL;
END;
$$
LANGUAGE plpgsql;

After creating the function, we create a trigger which calls the trigger function:

CREATE TRIGGER insert_measurement_trigger  
BEFORE INSERT ON measurement  
FOR EACH ROW EXECUTE FUNCTION measurement_insert_trigger();

We must redefine the trigger function each month so that it always inserts into the current child table. The trigger definition does not need to be updated, however.
We might want to insert data and have the server automatically locate the child table into which the row should be added. We could do this with a more complex trigger function, for example:

```sql
CREATE OR REPLACE FUNCTION measurement_insert_trigger()
RETURNS TRIGGER AS $$
BEGIN
    IF ( NEW.logdate >= DATE '2006-02-01' AND
         NEW.logdate < DATE '2006-03-01' ) THEN
        INSERT INTO measurement_y2006m02 VALUES (NEW.*);
    ELSIF ( NEW.logdate >= DATE '2006-03-01' AND
            NEW.logdate < DATE '2006-04-01' ) THEN
        INSERT INTO measurement_y2006m03 VALUES (NEW.*);
    ... 
    ELSIF ( NEW.logdate >= DATE '2008-01-01' AND
            NEW.logdate < DATE '2008-02-01' ) THEN
        INSERT INTO measurement_y2008m01 VALUES (NEW.*);
    ELSE
        RAISE EXCEPTION 'Date out of range. Fix the measurement_insert_trigger()
    function!';
    END IF;
    RETURN NULL;
END;
$$
LANGUAGE plpgsql;
```

The trigger definition is the same as before. Note that each `IF` test must exactly match the `CHECK` constraint for its child table.

While this function is more complex than the single-month case, it doesn't need to be updated as often, since branches can be added in advance of being needed.

---

**Note**

In practice, it might be best to check the newest child first, if most inserts go into that child. For simplicity, we have shown the trigger's tests in the same order as in other parts of this example.

A different approach to redirecting inserts into the appropriate child table is to set up rules, instead of a trigger, on the root table. For example:

```sql
CREATE RULE measurement_insert_y2006m02 AS
ON INSERT TO measurement WHERE
    ( logdate >= DATE '2006-02-01' AND logdate < DATE '2006-03-01' )
DO INSTEAD
    INSERT INTO measurement_y2006m02 VALUES (NEW.*);
...
CREATE RULE measurement_insert_y2008m01 AS
ON INSERT TO measurement WHERE
    ( logdate >= DATE '2008-01-01' AND logdate < DATE '2008-02-01' )
DO INSTEAD
```
A rule has significantly more overhead than a trigger, but the overhead is paid once per query rather than once per row, so this method might be advantageous for bulk-insert situations. In most cases, however, the trigger method will offer better performance.

Be aware that \texttt{COPY} ignores rules. If you want to use \texttt{COPY} to insert data, you'll need to copy into the correct child table rather than directly into the root. \texttt{COPY} does fire triggers, so you can use it normally if you use the trigger approach.

Another disadvantage of the rule approach is that there is no simple way to force an error if the set of rules doesn't cover the insertion date; the data will silently go into the root table instead.

6. Ensure that the \texttt{constraint exclusion} configuration parameter is not disabled in \texttt{postgresql.conf}; otherwise child tables may be accessed unnecessarily.

As we can see, a complex table hierarchy could require a substantial amount of DDL. In the above example we would be creating a new child table each month, so it might be wise to write a script that generates the required DDL automatically.

\section*{Maintenance for Inheritance Partitioning}

To remove old data quickly, simply drop the child table that is no longer necessary:

\begin{verbatim}
DROP TABLE measurement_y2006m02;
\end{verbatim}

To remove the child table from the inheritance hierarchy table but retain access to it as a table in its own right:

\begin{verbatim}
ALTER TABLE measurement_y2006m02 NO INHERIT measurement;
\end{verbatim}

To add a new child table to handle new data, create an empty child table just as the original children were created above:

\begin{verbatim}
CREATE TABLE measurement_y2008m02 (  
   CHECK ( logdate >= DATE '2008-02-01' AND logdate < DATE '2008-03-01' )  
) INHERITS (measurement);
\end{verbatim}

Alternatively, one may want to create and populate the new child table before adding it to the table hierarchy. This could allow data to be loaded, checked, and transformed before being made visible to queries on the parent table.

\begin{verbatim}
CREATE TABLE measurement_y2008m02  
   (LIKE measurement INCLUDING DEFAULTS INCLUDING CONSTRAINTS);  
ALTER TABLE measurement_y2008m02 ADD CONSTRAINT y2008m02  
   CHECK ( logdate >= DATE '2008-02-01' AND logdate < DATE '2008-03-01' );  
\copy measurement_y2008m02 from 'measurement_y2008m02'  
   -- possibly some other data preparation work  
ALTER TABLE measurement_y2008m02 INHERIT measurement;
\end{verbatim}

\section*{Caveats}

The following caveats apply to partitioning implemented using inheritance:

- There is no automatic way to verify that all of the \texttt{CHECK} constraints are mutually exclusive. It is safer to create code that generates child tables and creates and/or modifies associated objects than to write each by hand.

- Indexes and foreign key constraints apply to single tables and not to their inheritance children, hence they have some \texttt{caveats} to be aware of.

- The schemes shown here assume that the values of a row's key column(s) never change, or at least do not change enough to require it to move to another partition. An \texttt{UPDATE} that attempts to do that will fail because of the \texttt{CHECK} constraints. If you need to handle such cases, you can put
suitable update triggers on the child tables, but it makes management of the structure much more complicated.

- If you are using manual `VACUUM` or `ANALYZE` commands, don't forget that you need to run them on each child table individually. A command like:

  ```
  ANALYZE measurement;
  ```

  will only process the root table.

- `INSERT` statements with `ON CONFLICT` clauses are unlikely to work as expected, as the `ON CONFLICT` action is only taken in case of unique violations on the specified target relation, not its child relations.

- Triggers or rules will be needed to route rows to the desired child table, unless the application is explicitly aware of the partitioning scheme. Triggers may be complicated to write, and will be much slower than the tuple routing performed internally by declarative partitioning.

### 5.11.4. Partition Pruning

*Partition pruning* is a query optimization technique that improves performance for declaratively partitioned tables. As an example:

```sql
SET enable_partition_pruning = on;  -- the default
SELECT count(*) FROM measurement WHERE logdate >= '2008-01-01';
```

Without partition pruning, the above query would scan each of the partitions of the `measurement` table. With partition pruning enabled, the planner will examine the definition of each partition and prove that the partition need not be scanned because it could not contain any rows meeting the query's `WHERE` clause. When the planner can prove this, it excludes (prunes) the partition from the query plan.

By using the `EXPLAIN` command and the `enable_partition_pruning` configuration parameter, it's possible to show the difference between a plan for which partitions have been pruned and one for which they have not. A typical unoptimized plan for this type of table setup is:

```sql
SET enable_partition_pruning = off;
EXPLAIN SELECT count(*) FROM measurement WHERE logdate >= '2008-01-01';
```

```sql
QUERY PLAN
-----------------------------------------------------------------------------------
Aggregate  (cost=188.76..188.77 rows=1 width=8)
   ->  Append  (cost=0.00..181.05 rows=3085 width=0)
      ->  Seq Scan on measurement_y2006m02  (cost=0.00..33.12 rows=617 width=0)  
          Filter: (logdate >= '2008-01-01'::date)
      ->  Seq Scan on measurement_y2006m03  (cost=0.00..33.12 rows=617 width=0)  
          Filter: (logdate >= '2008-01-01'::date)
      ...
      ->  Seq Scan on measurement_y2007m11  (cost=0.00..33.12 rows=617 width=0)  
          Filter: (logdate >= '2008-01-01'::date)
      ->  Seq Scan on measurement_y2007m12  (cost=0.00..33.12 rows=617 width=0)  
          Filter: (logdate >= '2008-01-01'::date)
      ->  Seq Scan on measurement_y2008m01  (cost=0.00..33.12 rows=617 width=0)  
          Filter: (logdate >= '2008-01-01'::date)

Some or all of the partitions might use index scans instead of full-table sequential scans, but the point here is that there is no need to scan the older partitions at all to answer this query. When we enable partition pruning, we get a significantly cheaper plan that will deliver the same answer:

```sql
SET enable_partition_pruning = on;
EXPLAIN SELECT count(*) FROM measurement WHERE logdate >= '2008-01-01';
```

```sql
QUERY PLAN
-----------------------------------------------------------------------------------
Aggregate  (cost=37.75..37.76 rows=1 width=8)
   ->  Seq Scan on measurement_y2008m01  (cost=0.00..33.12 rows=617 width=0)
```

82
Filter: (logdate >= '2008-01-01'::date)

Note that partition pruning is driven only by the constraints defined implicitly by the partition keys, not by the presence of indexes. Therefore it isn't necessary to define indexes on the key columns. Whether an index needs to be created for a given partition depends on whether you expect that queries that scan the partition will generally scan a large part of the partition or just a small part. An index will be helpful in the latter case but not the former.

Partition pruning can be performed not only during the planning of a given query, but also during its execution. This is useful as it can allow more partitions to be pruned when clauses contain expressions whose values are not known at query planning time, for example, parameters defined in a `PREPARE` statement, using a value obtained from a subquery, or using a parameterized value on the inner side of a nested loop join. Partition pruning during execution can be performed at any of the following times:

- During initialization of the query plan. Partition pruning can be performed here for parameter values which are known during the initialization phase of execution. Partitions which are pruned during this stage will not show up in the query's `EXPLAIN` or `EXPLAIN ANALYZE`. It is possible to determine the number of partitions which were removed during this phase by observing the "Subplans Removed" property in the `EXPLAIN` output.

- During actual execution of the query plan. Partition pruning may also be performed here to remove partitions using values which are only known during actual query execution. This includes values from subqueries and values from execution-time parameters such as those from parameterized nested loop joins. Since the value of these parameters may change many times during the execution of the query, partition pruning is performed whenever one of the execution parameters being used by partition pruning changes. Determining if partitions were pruned during this phase requires careful inspection of the `loops` property in the `EXPLAIN ANALYZE` output. Subplans corresponding to different partitions may have different values for it depending on how many times each of them was pruned during execution. Some may be shown as (never executed) if they were pruned every time.

Partition pruning can be disabled using the `enable_partition_pruning` setting.

### 5.11.5. Partitioning and Constraint Exclusion

*Constraint exclusion* is a query optimization technique similar to partition pruning. While it is primarily used for partitioning implemented using the legacy inheritance method, it can be used for other purposes, including with declarative partitioning.

Constraint exclusion works in a very similar way to partition pruning, except that it uses each table's `CHECK` constraints — which gives it its name — whereas partition pruning uses the table's partition bounds, which exist only in the case of declarative partitioning. Another difference is that constraint exclusion is only applied at plan time; there is no attempt to remove partitions at execution time.

The fact that constraint exclusion uses `CHECK` constraints, which makes it slow compared to partition pruning, can sometimes be used as an advantage: because constraints can be defined even on declaratively-partitioned tables, in addition to their internal partition bounds, constraint exclusion may be able to elide additional partitions from the query plan.

The default (and recommended) setting of `constraint_exclusion` is neither `on` nor `off`, but an intermediate setting called `partition`, which causes the technique to be applied only to queries that are likely to be working on inheritance partitioned tables. The `on` setting causes the planner to examine `CHECK` constraints in all queries, even simple ones that are unlikely to benefit.

The following caveats apply to constraint exclusion:

- Constraint exclusion is only applied during query planning, unlike partition pruning, which can also be applied during query execution.

- Constraint exclusion only works when the query's `WHERE` clause contains constants (or externally supplied parameters). For example, a comparison against a non-immutable function such as
CURRENT_TIMESTAMP cannot be optimized, since the planner cannot know which child table the function’s value might fall into at run time.

- Keep the partitioning constraints simple, else the planner may not be able to prove that child tables might not need to be visited. Use simple equality conditions for list partitioning, or simple range tests for range partitioning, as illustrated in the preceding examples. A good rule of thumb is that partitioning constraints should contain only comparisons of the partitioning column(s) to constants using B-tree-indexable operators, because only B-tree-indexable column(s) are allowed in the partition key.

- All constraints on all children of the parent table are examined during constraint exclusion, so large numbers of children are likely to increase query planning time considerably. So the legacy inheritance based partitioning will work well with up to perhaps a hundred child tables; don’t try to use many thousands of children.

### 5.11.6. Best Practices for Declarative Partitioning

The choice of how to partition a table should be made carefully, as the performance of query planning and execution can be negatively affected by poor design.

One of the most critical design decisions will be the column or columns by which you partition your data. Often the best choice will be to partition by the column or set of columns which most commonly appear in `WHERE` clauses of queries being executed on the partitioned table. `WHERE` clauses that are compatible with the partition bound constraints can be used to prune unneeded partitions. However, you may be forced into making other decisions by requirements for the `primary key` or a `unique` constraint. Removal of unwanted data is also a factor to consider when planning your partitioning strategy. An entire partition can be detached fairly quickly, so it may be beneficial to design the partition strategy in such a way that all data to be removed at once is located in a single partition.

Choosing the target number of partitions that the table should be divided into is also a critical decision to make. Not having enough partitions may mean that indexes remain too large and that data locality remains poor which could result in low cache hit ratios. However, dividing the table into too many partitions can also cause issues. Too many partitions can mean longer query planning times and higher memory consumption during both query planning and execution, as further described below. When choosing how to partition your table, it's also important to consider what changes may occur in the future. For example, if you choose to have one partition per customer and you currently have a small number of large customers, consider the implications if in several years you instead find yourself with a large number of small customers. In this case, it may be better to choose to partition by `HASH` and choose a reasonable number of partitions rather than trying to partition by `LIST` and hoping that the number of customers does not increase beyond what it is practical to partition the data by.

Sub-partitioning can be useful to further divide partitions that are expected to become larger than other partitions. Another option is to use range partitioning with multiple columns in the partition key. Either of these can easily lead to excessive numbers of partitions, so restraint is advisable.

It is important to consider the overhead of partitioning during query planning and execution. The query planner is generally able to handle partition hierarchies with up to a few thousand partitions fairly well, provided that typical queries allow the query planner to prune all but a small number of partitions. Planning times become longer and memory consumption becomes higher when more partitions remain after the planner performs partition pruning. Another reason to be concerned about having a large number of partitions is that the server’s memory consumption may grow significantly over time, especially if many sessions touch large numbers of partitions. That’s because each partition requires its metadata to be loaded into the local memory of each session that touches it.

With data warehouse type workloads, it can make sense to use a larger number of partitions than with an OLTP type workload. Generally, in data warehouses, query planning time is less of a concern as the majority of processing time is spent during query execution. With either of these two types of workload, it is important to make the right decisions early, as re-partitioning large quantities of data can be painfully slow. Simulations of the intended workload are often beneficial for optimizing the partitioning strategy. Never just assume that more partitions are better than fewer partitions, nor vice-versa.
5.12. Foreign Data

Postgres Pro implements portions of the SQL/MED specification, allowing you to access data that resides outside Postgres Pro using regular SQL queries. Such data is referred to as foreign data. (Note that this usage is not to be confused with foreign keys, which are a type of constraint within the database.)

Foreign data is accessed with help from a foreign data wrapper. A foreign data wrapper is a library that can communicate with an external data source, hiding the details of connecting to the data source and obtaining data from it. There are some foreign data wrappers available as contrib modules; see Appendix F. Other kinds of foreign data wrappers might be found as third party products. If none of the existing foreign data wrappers suit your needs, you can write your own; see Chapter 53.

To access foreign data, you need to create a foreign server object, which defines how to connect to a particular external data source according to the set of options used by its supporting foreign data wrapper. Then you need to create one or more foreign tables, which define the structure of the remote data. A foreign table can be used in queries just like a normal table, but a foreign table has no storage in the Postgres Pro server. Whenever it is used, Postgres Pro asks the foreign data wrapper to fetch data from the external source, or transmit data to the external source in the case of update commands.

Accessing remote data may require authenticating to the external data source. This information can be provided by a user mapping, which can provide additional data such as user names and passwords based on the current Postgres Pro role.

For additional information, see CREATE FOREIGN DATA WRAPPER, CREATE SERVER, CREATE USER MAPPING, CREATE FOREIGN TABLE, and IMPORT FOREIGN SCHEMA.

5.13. Other Database Objects

Tables are the central objects in a relational database structure, because they hold your data. But they are not the only objects that exist in a database. Many other kinds of objects can be created to make the use and management of the data more efficient or convenient. They are not discussed in this chapter, but we give you a list here so that you are aware of what is possible:

- Views
- Functions, procedures, and operators
- Data types and domains
- Triggers and rewrite rules

Detailed information on these topics appears in Part V.

5.14. Dependency Tracking

When you create complex database structures involving many tables with foreign key constraints, views, triggers, functions, etc. you implicitly create a net of dependencies between the objects. For instance, a table with a foreign key constraint depends on the table it references.

To ensure the integrity of the entire database structure, Postgres Pro makes sure that you cannot drop objects that other objects still depend on. For example, attempting to drop the products table we considered in Section 5.4.5, with the orders table depending on it, would result in an error message like this:

```
DROP TABLE products;
```

```
ERROR:  cannot drop table products because other objects depend on it
DETAIL:  constraint orders_product_no_fkey on table orders depends on table products
HINT:  Use DROP ... CASCADE to drop the dependent objects too.
```

The error message contains a useful hint: if you do not want to bother deleting all the dependent objects individually, you can run:
Data Definition

DROP TABLE products CASCADE;

and all the dependent objects will be removed, as will any objects that depend on them, recursively. In 
this case, it doesn't remove the orders table, it only removes the foreign key constraint. It stops there 
because nothing depends on the foreign key constraint. (If you want to check what DROP ... CASCADE 
will do, run DROP without CASCADE and read the DETAIL output.)

Almost all DROP commands in Postgres Pro support specifying CASCADE. Of course, the nature of the 
possible dependencies varies with the type of the object. You can also write RESTRICT instead of CASCADE 
to get the default behavior, which is to prevent dropping objects that any other objects depend on.

Note

According to the SQL standard, specifying either RESTRICT or CASCADE is required in a DROP 
command. No database system actually enforces that rule, but whether the default behavior is 
RESTRICT or CASCADE varies across systems.

If a DROP command lists multiple objects, CASCADE is only required when there are dependencies outside 
the specified group. For example, when saying DROP TABLE tab1, tab2 the existence of a foreign key 
referring tab1 from tab2 would not mean that CASCADE is needed to succeed.

For user-defined functions, Postgres Pro tracks dependencies associated with a function's externally-
visible properties, such as its argument and result types, but not dependencies that could only be known 
by examining the function body. As an example, consider this situation:

CREATE TYPE rainbow AS ENUM ('red', 'orange', 'yellow',
    'green', 'blue', 'purple');

CREATE TABLE my_colors (color rainbow, note text);

CREATE FUNCTION get_color_note (rainbow) RETURNS text AS
    'SELECT note FROM my_colors WHERE color = $1'
    LANGUAGE SQL;

(See Section 36.5 for an explanation of SQL-language functions.) Postgres Pro will be aware that the 
get_color_note function depends on the rainbow type: dropping the type would force dropping the 
function, because its argument type would no longer be defined. But Postgres Pro will not consider 
get_color_note to depend on the my_colors table, and so will not drop the function if the table is 
dropped. While there are disadvantages to this approach, there are also benefits. The function is still 
valid in some sense if the table is missing, though executing it would cause an error; creating a new 
table of the same name would allow the function to work again.
Chapter 6. Data Manipulation

The previous chapter discussed how to create tables and other structures to hold your data. Now it is time to fill the tables with data. This chapter covers how to insert, update, and delete table data. The chapter after this will finally explain how to extract your long-lost data from the database.

6.1. Inserting Data

When a table is created, it contains no data. The first thing to do before a database can be of much use is to insert data. Data is inserted one row at a time. You can also insert more than one row in a single command, but it is not possible to insert something that is not a complete row. Even if you know only some column values, a complete row must be created.

To create a new row, use the INSERT command. The command requires the table name and column values. For example, consider the products table from Chapter 5:

```sql
CREATE TABLE products (
    product_no integer,
    name text,
    price numeric
);
```

An example command to insert a row would be:

```sql
INSERT INTO products VALUES (1, 'Cheese', 9.99);
```

The data values are listed in the order in which the columns appear in the table, separated by commas. Usually, the data values will be literals (constants), but scalar expressions are also allowed.

The above syntax has the drawback that you need to know the order of the columns in the table. To avoid this you can also list the columns explicitly. For example, both of the following commands have the same effect as the one above:

```sql
INSERT INTO products (product_no, name, price) VALUES (1, 'Cheese', 9.99);
INSERT INTO products (name, price, product_no) VALUES ('Cheese', 9.99, 1);
```

Many users consider it good practice to always list the column names.

If you don't have values for all the columns, you can omit some of them. In that case, the columns will be filled with their default values. For example:

```sql
INSERT INTO products (product_no, name) VALUES (1, 'Cheese');
INSERT INTO products VALUES (1, 'Cheese');
```

The second form is a Postgres Pro extension. It fills the columns from the left with as many values as are given, and the rest will be defaulted.

For clarity, you can also request default values explicitly, for individual columns or for the entire row:

```sql
INSERT INTO products (product_no, name, price) VALUES (1, 'Cheese', DEFAULT);
INSERT INTO products DEFAULT VALUES;
```

You can insert multiple rows in a single command:

```sql
INSERT INTO products (product_no, name, price) VALUES
    (1, 'Cheese', 9.99),
    (2, 'Bread', 1.99),
    (3, 'Milk', 2.99);
```

It is also possible to insert the result of a query (which might be no rows, one row, or many rows):

```sql
INSERT INTO products (product_no, name, price)
SELECT product_no, name, price FROM new_products
WHERE release_date = 'today';
```
This provides the full power of the SQL query mechanism (Chapter 7) for computing the rows to be inserted.

Tip

When inserting a lot of data at the same time, consider using the COPY command. It is not as flexible as the INSERT command, but is more efficient. Refer to Section 14.4 for more information on improving bulk loading performance.

6.2. Updating Data

The modification of data that is already in the database is referred to as updating. You can update individual rows, all the rows in a table, or a subset of all rows. Each column can be updated separately; the other columns are not affected.

To update existing rows, use the UPDATE command. This requires three pieces of information:

1. The name of the table and column to update
2. The new value of the column
3. Which row(s) to update

Recall from Chapter 5 that SQL does not, in general, provide a unique identifier for rows. Therefore it is not always possible to directly specify which row to update. Instead, you specify which conditions a row must meet in order to be updated. Only if you have a primary key in the table (independent of whether you declared it or not) can you reliably address individual rows by choosing a condition that matches the primary key. Graphical database access tools rely on this fact to allow you to update rows individually.

For example, this command updates all products that have a price of 5 to have a price of 10:

```
UPDATE products SET price = 10 WHERE price = 5;
```

This might cause zero, one, or many rows to be updated. It is not an error to attempt an update that does not match any rows.

Let’s look at that command in detail. First is the key word `UPDATE` followed by the table name. As usual, the table name can be schema-qualified, otherwise it is looked up in the path. Next is the key word `SET` followed by the column name, an equal sign, and the new column value. The new column value can be any scalar expression, not just a constant. For example, if you want to raise the price of all products by 10% you could use:

```
UPDATE products SET price = price * 1.10;
```

As you see, the expression for the new value can refer to the existing value(s) in the row. We also left out the `WHERE` clause. If it is omitted, it means that all rows in the table are updated. If it is present, only those rows that match the `WHERE` condition are updated. Note that the equals sign in the `SET` clause is an assignment while the one in the `WHERE` clause is a comparison, but this does not create any ambiguity. Of course, the `WHERE` condition does not have to be an equality test. Many other operators are available (see Chapter 9). But the expression needs to evaluate to a Boolean result.

You can update more than one column in an `UPDATE` command by listing more than one assignment in the `SET` clause. For example:

```
UPDATE mytable SET a = 5, b = 3, c = 1 WHERE a > 0;
```

6.3. Deleting Data

So far we have explained how to add data to tables and how to change data. What remains is to discuss how to remove data that is no longer needed. Just as adding data is only possible in whole rows, you can only remove entire rows from a table. In the previous section we explained that SQL does not provide a way to directly address individual rows. Therefore, removing rows can only be done by specifying
conditions that the rows to be removed have to match. If you have a primary key in the table then you can specify the exact row. But you can also remove groups of rows matching a condition, or you can remove all rows in the table at once.

You use the **DELETE** command to remove rows; the syntax is very similar to the **UPDATE** command. For instance, to remove all rows from the products table that have a price of 10, use:

```sql
DELETE FROM products WHERE price = 10;
```

If you simply write:

```sql
DELETE FROM products;
```

then all rows in the table will be deleted! Caveat programmer.

## 6.4. Returning Data from Modified Rows

Sometimes it is useful to obtain data from modified rows while they are being manipulated. The **INSERT**, **UPDATE**, and **DELETE** commands all have an optional **RETURNING** clause that supports this. Use of **RETURNING** avoids performing an extra database query to collect the data, and is especially valuable when it would otherwise be difficult to identify the modified rows reliably.

The allowed contents of a **RETURNING** clause are the same as a **SELECT** command's output list (see Section 7.3). It can contain column names of the command's target table, or value expressions using those columns. A common shorthand is **RETURNING \*\**, which selects all columns of the target table in order.

In an **INSERT**, the data available to **RETURNING** is the row as it was inserted. This is not so useful in trivial inserts, since it would just repeat the data provided by the client. But it can be very handy when relying on computed default values. For example, when using a **serial** column to provide unique identifiers, **RETURNING** can return the ID assigned to a new row:

```sql
CREATE TABLE users (firstname text, lastname text, id serial primary key);

INSERT INTO users (firstname, lastname) VALUES ('Joe', 'Cool') RETURNING id;
```

The **RETURNING** clause is also very useful with **INSERT ... SELECT**.

In an **UPDATE**, the data available to **RETURNING** is the new content of the modified row. For example:

```sql
UPDATE products SET price = price * 1.10
WHERE price <= 99.99
RETURNING name, price AS new_price;
```

In a **DELETE**, the data available to **RETURNING** is the content of the deleted row. For example:

```sql
DELETE FROM products
WHERE obsoletion_date = 'today'
RETURNING *;
```

If there are triggers (Chapter 37) on the target table, the data available to **RETURNING** is the row as modified by the triggers. Thus, inspecting columns computed by triggers is another common use-case for **RETURNING**.
Chapter 7. Queries

The previous chapters explained how to create tables, how to fill them with data, and how to manipulate that data. Now we finally discuss how to retrieve the data from the database.

7.1. Overview

The process of retrieving or the command to retrieve data from a database is called a query. In SQL the \texttt{SELECT} command is used to specify queries. The general syntax of the \texttt{SELECT} command is

\[ \text{WITH with_queries} \] \texttt{SELECT select_list FROM table_expression [sort_specification]} \]

The following sections describe the details of the select list, the table expression, and the sort specification. \texttt{WITH} queries are treated last since they are an advanced feature.

A simple kind of query has the form:

\texttt{SELECT \ast FROM table1;}

Assuming that there is a table called \texttt{table1}, this command would retrieve all rows and all user-defined columns from \texttt{table1}. (The method of retrieval depends on the client application. For example, the psql program will display an ASCII-art table on the screen, while client libraries will offer functions to extract individual values from the query result.) The select list specification \texttt{\ast} means all columns that the table expression happens to provide. A select list can also select a subset of the available columns or make calculations using the columns. For example, if \texttt{table1} has columns named \texttt{a}, \texttt{b}, and \texttt{c} (and perhaps others) you can make the following query:

\texttt{SELECT a, b + c FROM table1;}

(assuming that \texttt{b} and \texttt{c} are of a numerical data type). See Section 7.3 for more details.

\texttt{FROM table1} is a simple kind of table expression: it reads just one table. In general, table expressions can be complex constructs of base tables, joins, and subqueries. But you can also omit the table expression entirely and use the \texttt{SELECT} command as a calculator:

\texttt{SELECT 3 * 4;}

This is more useful if the expressions in the select list return varying results. For example, you could call a function this way:

\texttt{SELECT random();}

7.2. Table Expressions

A \textit{table expression} computes a table. The table expression contains a \texttt{FROM} clause that is optionally followed by \texttt{WHERE}, \texttt{GROUP BY}, and \texttt{HAVING} clauses. Trivial table expressions simply refer to a table on disk, a so-called base table, but more complex expressions can be used to modify or combine base tables in various ways.

The optional \texttt{WHERE}, \texttt{GROUP BY}, and \texttt{HAVING} clauses in the table expression specify a pipeline of successive transformations performed on the table derived in the \texttt{FROM} clause. All these transformations produce a virtual table that provides the rows that are passed to the select list to compute the output rows of the query.

7.2.1. The \texttt{FROM} Clause

The \texttt{FROM} clause derives a table from one or more other tables given in a comma-separated table reference list.

\texttt{FROM table_reference [, table_reference [, ...]]}

A table reference can be a table name (possibly schema-qualified), or a derived table such as a subquery, a \texttt{JOIN} construct, or complex combinations of these. If more than one table reference is listed in the \texttt{FROM}
clause, the tables are cross-joined (that is, the Cartesian product of their rows is formed; see below). The result of the FROM list is an intermediate virtual table that can then be subject to transformations by the WHERE, GROUP BY, and HAVING clauses and is finally the result of the overall table expression.

When a table reference names a table that is the parent of a table inheritance hierarchy, the table reference produces rows of not only that table but all of its descendant tables, unless the key word ONLY precedes the table name. However, the reference produces only the columns that appear in the named table — any columns added in subtables are ignored.

Instead of writing ONLY before the table name, you can write * after the table name to explicitly specify that descendant tables are included. There is no real reason to use this syntax any more, because searching descendant tables is now always the default behavior. However, it is supported for compatibility with older releases.

### 7.2.1.1. Joined Tables

A joined table is a table derived from two other (real or derived) tables according to the rules of the particular join type. Inner, outer, and cross-joins are available. The general syntax of a joined table is

\[
T_1 \ join\_type \ T_2 \ [\ join\_condition \ ]
\]

Joins of all types can be chained together, or nested: either or both \( T_1 \) and \( T_2 \) can be joined tables. Parentheses can be used around JOIN clauses to control the join order. In the absence of parentheses, JOIN clauses nest left-to-right.

#### Join Types

**Cross join**

\[
T_1 \ CROSS JOIN \ T_2
\]

For every possible combination of rows from \( T_1 \) and \( T_2 \) (i.e., a Cartesian product), the joined table will contain a row consisting of all columns in \( T_1 \) followed by all columns in \( T_2 \). If the tables have \( N \) and \( M \) rows respectively, the joined table will have \( N \times M \) rows.

\[
\text{FROM} \ T_1 \ CROSS JOIN \ T_2 \ is \ equivalent \ to \ FROM \ T_1 \ INNER JOIN \ T_2 \ ON \ TRUE \ (see \ below) \ It \ is \ also \ equivalent \ to \ FROM \ T_1, \ T_2.
\]

**Qualified joins**

\[
T_1 \ {\ [\text{INNER}] \ | \ {\ LEFT \ | \ RIGHT \ | \ FULL \ } \ [\text{OUTER}] \ } \ JOIN \ T_2 \ ON \ boolean\_expression\]
\[
T_1 \ {\ [\text{INNER}] \ | \ {\ LEFT \ | \ RIGHT \ | \ FULL \ } \ [\text{OUTER}] \ } \ JOIN \ T_2 \ USING ( \ join\_column\_list \ )
\[
T_1 \ NATURAL {\ [\text{INNER}] \ | \ {\ LEFT \ | \ RIGHT \ | \ FULL \ } \ [\text{OUTER}] \ } \ JOIN \ T_2
\]

The words INNER and OUTER are optional in all forms. INNER is the default; LEFT, RIGHT, and FULL imply an outer join.

The join condition is specified in the ON or USING clause, or implicitly by the word NATURAL. The join condition determines which rows from the two source tables are considered to “match”, as explained in detail below.

The possible types of qualified join are:

---

*Note*

This latter equivalence does not hold exactly when more than two tables appear, because JOIN binds more tightly than comma. For example \( \text{FROM} \ T_1 \ CROSS JOIN \ T_2 \ INNER JOIN \ T_3 \ ON \ condition \) is not the same as \( \text{FROM} \ T_1, \ T_2 \ INNER JOIN \ T_3 \ ON \ condition \) because the condition can reference \( T_1 \) in the first case but not the second.
INNER JOIN

For each row R1 of T1, the joined table has a row for each row in T2 that satisfies the join condition with R1.

LEFT OUTER JOIN

First, an inner join is performed. Then, for each row in T1 that does not satisfy the join condition with any row in T2, a joined row is added with null values in columns of T2. Thus, the joined table always has at least one row for each row in T1.

RIGHT OUTER JOIN

First, an inner join is performed. Then, for each row in T2 that does not satisfy the join condition with any row in T1, a joined row is added with null values in columns of T1. This is the converse of a left join: the result table will always have a row for each row in T2.

FULL OUTER JOIN

First, an inner join is performed. Then, for each row in T1 that does not satisfy the join condition with any row in T2, a joined row is added with null values in columns of T2. Also, for each row of T2 that does not satisfy the join condition with any row in T1, a joined row with null values in the columns of T1 is added.

The ON clause is the most general kind of join condition: it takes a Boolean value expression of the same kind as is used in a WHERE clause. A pair of rows from T1 and T2 match if the ON expression evaluates to true.

The USING clause is a shorthand that allows you to take advantage of the specific situation where both sides of the join use the same name for the joining column(s). It takes a comma-separated list of the shared column names and forms a join condition that includes an equality comparison for each one. For example, joining T1 and T2 with USING (a, b) produces the join condition ON T1.a = T2.a AND T1.b = T2.b.

Furthermore, the output of JOIN USING suppresses redundant columns: there is no need to print both of the matched columns, since they must have equal values. While JOIN ON produces all columns from T1 followed by all columns from T2, JOIN USING produces one output column for each of the listed column pairs (in the listed order), followed by any remaining columns from T1, followed by any remaining columns from T2.

Finally, NATURAL is a shorthand form of USING: it forms a USING list consisting of all column names that appear in both input tables. As with USING, these columns appear only once in the output table. If there are no common column names, NATURAL JOIN behaves like JOIN ... ON TRUE, producing a cross-product join.

Note

USING is reasonably safe from column changes in the joined relations since only the listed columns are combined. NATURAL is considerably more risky since any schema changes to either relation that cause a new matching column name to be present will cause the join to combine that new column as well.

To put this together, assume we have tables t1:

<table>
<thead>
<tr>
<th>num</th>
<th>name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>a</td>
</tr>
<tr>
<td>2</td>
<td>b</td>
</tr>
<tr>
<td>3</td>
<td>c</td>
</tr>
</tbody>
</table>

and t2:
then we get the following results for the various joins:

```sql
=> SELECT * FROM t1 CROSS JOIN t2;
num | name | num | value
-----+------+-----+-------
1   | a    |   1 | xxx
1   | a    |   3 | yyy
1   | a    |   5 | zzz
2   | b    |   1 | xxx
2   | b    |   3 | yyy
2   | b    |   5 | zzz
3   | c    |   1 | xxx
3   | c    |   3 | yyy
3   | c    |   5 | zzz
(9 rows)
```

```sql
=> SELECT * FROM t1 INNER JOIN t2 ON t1.num = t2.num;
num | name | num | value
-----+------+-----+-------
1   | a    |   1 | xxx
3   | c    |   3 | yyy
(2 rows)
```

```sql
=> SELECT * FROM t1 INNER JOIN t2 USING (num);
num | name | value
-----+------+-------
1   | a    | xxx
3   | c    | yyy
(2 rows)
```

```sql
=> SELECT * FROM t1 NATURAL INNER JOIN t2;
num | name | value
-----+------+-------
1   | a    | xxx
3   | c    | yyy
(2 rows)
```

```sql
=> SELECT * FROM t1 LEFT JOIN t2 ON t1.num = t2.num;
num | name | num | value
-----+------+-----+-------
1   | a    |   1 | xxx
2   | b    |     |
3   | c    |   3 | yyy
(3 rows)
```

```sql
=> SELECT * FROM t1 LEFT JOIN t2 USING (num);
num | name | value
-----+------+-------
1   | a    | xxx
2   | b    |     |
3   | c    | yyy
(3 rows)
```
=> SELECT * FROM t1 RIGHT JOIN t2 ON t1.num = t2.num;
num | name | num | value
-----+------|-----+-------
 1   | a    | 1   | xxx
 3   | c    | 3   | yyy
   |      | 5   | zzz
(3 rows)

=> SELECT * FROM t1 FULL JOIN t2 ON t1.num = t2.num;
num | name | num | value
-----+------|-----+-------
 1   | a    | 1   | xxx
 2   | b    |     |
 3   | c    | 3   | yyy
   |      | 5   | zzz
(4 rows)

The join condition specified with ON can also contain conditions that do not relate directly to the join. This can prove useful for some queries but needs to be thought out carefully. For example:

=> SELECT * FROM t1 LEFT JOIN t2 ON t1.num = t2.num AND t2.value = 'xxx';
num | name | num | value
-----+------|-----+-------
 1   | a    | 1   | xxx
 2   | b    |     |
 3   | c    |     |
(3 rows)

Notice that placing the restriction in the WHERE clause produces a different result:

=> SELECT * FROM t1 LEFT JOIN t2 ON t1.num = t2.num WHERE t2.value = 'xxx';
num | name | num | value
-----+------|-----+-------
 1   | a    | 1   | xxx
(1 row)

This is because a restriction placed in the ON clause is processed before the join, while a restriction placed in the WHERE clause is processed after the join. That does not matter with inner joins, but it matters a lot with outer joins.

7.2.1.2. Table and Column Aliases

A temporary name can be given to tables and complex table references to be used for references to the derived table in the rest of the query. This is called a table alias.

To create a table alias, write

```
FROM table_reference AS alias
```

or

```
FROM table_reference alias
```

The AS key word is optional noise. alias can be any identifier.

A typical application of table aliases is to assign short identifiers to long table names to keep the join clauses readable. For example:

```
SELECT * FROM some_very_long_table_name s JOIN another_fairly_long_name a ON s.id = a.num;
```

The alias becomes the new name of the table reference so far as the current query is concerned — it is not allowed to refer to the table by the original name elsewhere in the query. Thus, this is not valid:
SELECT * FROM my_table AS m WHERE my_table.a > 5; -- wrong

Table aliases are mainly for notational convenience, but it is necessary to use them when joining a table to itself, e.g.:

SELECT * FROM people AS mother JOIN people AS child ON mother.id = child.mother_id;

Additionally, an alias is required if the table reference is a subquery (see Section 7.2.1.3).

Parentheses are used to resolve ambiguities. In the following example, the first statement assigns the alias b to the second instance of my_table, but the second statement assigns the alias to the result of the join:

SELECT * FROM my_table AS a CROSS JOIN my_table AS b ... 
SELECT * FROM (my_table AS a CROSS JOIN my_table) AS b ... 

Another form of table aliasing gives temporary names to the columns of the table, as well as the table itself:

FROM table_reference [AS] alias ( column1 [, column2 [, ...]] )

If fewer column aliases are specified than the actual table has columns, the remaining columns are not renamed. This syntax is especially useful for self-joins or subqueries.

When an alias is applied to the output of a JOIN clause, the alias hides the original name(s) within the JOIN. For example:

SELECT a.* FROM my_table AS a JOIN your_table AS b ON ...  
is valid SQL, but:

SELECT a.* FROM (my_table AS a JOIN your_table AS b ON ...) AS c

is not valid; the table alias a is not visible outside the alias c.

7.2.1.3. Subqueries

Subqueries specifying a derived table must be enclosed in parentheses and must be assigned a table alias name (as in Section 7.2.1.2). For example:

FROM (SELECT * FROM table1) AS alias_name

This example is equivalent to FROM table1 AS alias_name. More interesting cases, which cannot be reduced to a plain join, arise when the subquery involves grouping or aggregation.

A subquery can also be a VALUES list:

FROM (VALUES ('anne', 'smith'), ('bob', 'jones'), ('joe', 'blow')) AS names(first, last)

Again, a table alias is required. Assigning alias names to the columns of the VALUES list is optional, but is good practice. For more information see Section 7.7.

7.2.1.4. Table Functions

Table functions are functions that produce a set of rows, made up of either base data types (scalar types) or composite data types (table rows). They are used like a table, view, or subquery in the FROM clause of a query. Columns returned by table functions can be included in SELECT, JOIN, or WHERE clauses in the same manner as columns of a table, view, or subquery.

Table functions may also be combined using the ROWS FROM syntax, with the results returned in parallel columns; the number of result rows in this case is that of the largest function result, with smaller results padded with null values to match.
If the `WITH ORDINALITY` clause is specified, an additional column of type `bigint` will be added to the function result columns. This column numbers the rows of the function result set, starting from 1. (This is a generalization of the SQL-standard syntax for `UNNEST ... WITH ORDINALITY`.) By default, the ordinal column is called `ordinality`, but a different column name can be assigned to it using an `AS` clause.

The special table function `UNNEST` may be called with any number of array parameters, and it returns a corresponding number of columns, as if `UNNEST` (Section 9.19) had been called on each parameter separately and combined using the `ROWS FROM` construct.

```sql
UNNEST( array_expression [, ... ] ) [WITH ORDINALITY] [[AS] table_alias [(column_alias [, ... ])]]
```

If no `table_alias` is specified, the function name is used as the table name; in the case of a `ROWS FROM()` construct, the first function's name is used.

If column aliases are not supplied, then for a function returning a base data type, the column name is also the same as the function name. For a function returning a composite type, the result columns get the names of the individual attributes of the type.

Some examples:

```sql
CREATE TABLE foo (fooid int, foosubid int, fooname text);

CREATE FUNCTION getfoo(int) RETURNS SETOF foo AS $$
SELECT * FROM foo WHERE fooid = $1;
$$ LANGUAGE SQL;

SELECT * FROM getfoo(1) AS t1;

SELECT * FROM foo
WHERE foosubid IN (
    SELECT foosubid
    FROM getfoo(foo.fooid) z
    WHERE z.fooid = foo.fooid
);

CREATE VIEW vw_getfoo AS SELECT * FROM getfoo(1);

SELECT * FROM vw_getfoo;
```

In some cases it is useful to define table functions that can return different column sets depending on how they are invoked. To support this, the table function can be declared as returning the pseudo-type `record` with no `OUT` parameters. When such a function is used in a query, the expected row structure must be specified in the query itself, so that the system can know how to parse and plan the query. This syntax looks like:

```sql
function_call [AS] alias (column_definition [, ... ])
function_call AS [alias] (column_definition [, ... ])
ROWS FROM( ... function_call AS (column_definition [, ... ]) [, ... ] )
```

When not using the `ROWS FROM()` syntax, the `column_definition` list replaces the column alias list that could otherwise be attached to the `FROM` item; the names in the column definitions serve as column aliases. When using the `ROWS FROM()` syntax, a `column_definition` list can be attached to each member function separately; or if there is only one member function and no `WITH ORDINALITY` clause, a `column_definition` list can be written in place of a column alias list following `ROWS FROM()`.

Consider this example:

```sql
SELECT *
FROM dblink('dbname=mydb', 'SELECT pronoame, prosrc FROM pg_proc')
AS t1(pronoame name, prosrc text)
```
WHERE proname LIKE 'bytea%';

The dblink function (part of the dblink module) executes a remote query. It is declared to return record since it might be used for any kind of query. The actual column set must be specified in the calling query so that the parser knows, for example, what * should expand to.

This example uses ROWS FROM:

```sql
SELECT *
FROM ROWS FROM
{
    json_to_recordset('{{"a":40,"b":"foo"},{"a":"100","b":"bar"}}')
    AS (a INTEGER, b TEXT),
    generate_series(1, 3)
} AS x (p, q, s)
ORDER BY p;
```

<table>
<thead>
<tr>
<th>p</th>
<th>q</th>
<th>s</th>
</tr>
</thead>
<tbody>
<tr>
<td>40</td>
<td>foo</td>
<td>1</td>
</tr>
<tr>
<td>100</td>
<td>bar</td>
<td>2</td>
</tr>
<tr>
<td></td>
<td></td>
<td>3</td>
</tr>
</tbody>
</table>

It joins two functions into a single FROM target. json_to_recordset() is instructed to return two columns, the first integer and the second text. The result of generate_series() is used directly. The ORDER BY clause sorts the column values as integers.

### 7.2.1.5. LATERAL Subqueries

Subqueries appearing in FROM can be preceded by the key word LATERAL. This allows them to reference columns provided by preceding FROM items. (Without LATERAL, each subquery is evaluated independently and so cannot cross-reference any other FROM item.)

Table functions appearing in FROM can also be preceded by the key word LATERAL, but for functions the key word is optional; the function’s arguments can contain references to columns provided by preceding FROM items in any case.

A LATERAL item can appear at top level in the FROM list, or within a JOIN tree. In the latter case it can also refer to any items that are on the left-hand side of a JOIN that it is on the right-hand side of.

When a FROM item contains LATERAL cross-references, evaluation proceeds as follows: for each row of the FROM item providing the cross-referenced column(s), or set of rows of multiple FROM items providing the columns, the LATERAL item is evaluated using that row or row set’s values of the columns. The resulting row(s) are joined as usual with the rows they were computed from. This is repeated for each row or set of rows from the column source table(s).

A trivial example of LATERAL is

```sql
SELECT * FROM foo, LATERAL (SELECT * FROM bar WHERE bar.id = foo.bar_id) ss;
```

This is not especially useful since it has exactly the same result as the more conventional

```sql
SELECT * FROM foo, bar WHERE bar.id = foo.bar_id;
```

LATERAL is primarily useful when the cross-referenced column is necessary for computing the row(s) to be joined. A common application is providing an argument value for a set-returning function. For example, supposing that vertices(polygon) returns the set of vertices of a polygon, we could identify close-together vertices of polygons stored in a table with:

```sql
SELECT p1.id, p2.id, v1, v2
FROM polygons p1, polygons p2,
     LATERAL vertices(p1.poly) v1,
```
This query could also be written

```
SELECT p1.id, p2.id, v1, v2
FROM polygons p1 CROSS JOIN LATERAL vertices(p1.poly) v1,
    polygons p2 CROSS JOIN LATERAL vertices(p2.poly) v2
WHERE (v1 <-> v2) < 10 AND p1.id != p2.id;
```

or in several other equivalent formulations. (As already mentioned, the LATERAL key word is unnecessary in this example, but we use it for clarity.)

It is often particularly handy to LEFT JOIN to a LATERAL subquery, so that source rows will appear in the result even if the LATERAL subquery produces no rows for them. For example, if `get_product_names()` returns the names of products made by a manufacturer, but some manufacturers in our table currently produce no products, we could find out which ones those are like this:

```
SELECT m.name
FROM manufacturers m LEFT JOIN LATERAL get_product_names(m.id) pname ON true
WHERE pname IS NULL;
```

### 7.2.2. The WHERE Clause

The syntax of the WHERE clause is

```
WHERE search_condition
```

where `search_condition` is any value expression (see Section 4.2) that returns a value of type `boolean`.

After the processing of the FROM clause is done, each row of the derived virtual table is checked against the search condition. If the result of the condition is true, the row is kept in the output table, otherwise (i.e., if the result is false or null) it is discarded. The search condition typically references at least one column of the table generated in the FROM clause; this is not required, but otherwise the WHERE clause will be fairly useless.

---

**Note**

The join condition of an inner join can be written either in the WHERE clause or in the JOIN clause. For example, these table expressions are equivalent:

```
FROM a, b WHERE a.id = b.id AND b.val > 5
```

and:

```
FROM a INNER JOIN b ON (a.id = b.id) WHERE b.val > 5
```

or perhaps even:

```
FROM a NATURAL JOIN b WHERE b.val > 5
```

Which one of these you use is mainly a matter of style. The JOIN syntax in the FROM clause is probably not as portable to other SQL database management systems, even though it is in the SQL standard. For outer joins there is no choice: they must be done in the FROM clause. The ON or USING clause of an outer join is not equivalent to a WHERE condition, because it results in the addition of rows (for unmatched input rows) as well as the removal of rows in the final result.

---

Here are some examples of WHERE clauses:

```
SELECT ... FROM fdt WHERE c1 > 5
```

```
SELECT ... FROM fdt WHERE c1 IN (1, 2, 3)
```
SELECT ... FROM fdt WHERE c1 IN (SELECT c1 FROM t2)

SELECT ... FROM fdt WHERE c1 IN (SELECT c3 FROM t2 WHERE c2 = fdt.c1 + 10)

SELECT ... FROM fdt WHERE c1 BETWEEN (SELECT c3 FROM t2 WHERE c2 = fdt.c1 + 10) AND 100

SELECT ... FROM fdt WHERE EXISTS (SELECT c1 FROM t2 WHERE c2 > fdt.c1)

fdt is the table derived in the FROM clause. Rows that do not meet the search condition of the WHERE clause are eliminated from fdt. Notice the use of scalar subqueries as value expressions. Just like any other query, the subqueries can employ complex table expressions. Notice also how fdt is referenced in the subqueries. Qualifying c1 as fdt.c1 is only necessary if c1 is also the name of a column in the derived input table of the subquery. But qualifying the column name adds clarity even when it is not needed. This example shows how the column naming scope of an outer query extends into its inner queries.

7.2.3. The GROUP BY and HAVING Clauses

After passing the WHERE filter, the derived input table might be subject to grouping, using the GROUP BY clause, and elimination of group rows using the HAVING clause.

```
SELECT select_list
FROM ...
[WHERE ...]
GROUP BY grouping_column_reference [, grouping_column_reference]...
```

The GROUP BY clause is used to group together those rows in a table that have the same values in all the columns listed. The order in which the columns are listed does not matter. The effect is to combine each set of rows having common values into one group row that represents all rows in the group. This is done to eliminate redundancy in the output and/or compute aggregates that apply to these groups. For instance:

```
=> SELECT * FROM test1;
  x  | y
---+---
  a | 3
  c | 2
  b | 5
  a | 1
(4 rows)
```

```
=> SELECT x FROM test1 GROUP BY x;
  x
---
  a
  b
  c
(3 rows)
```

In the second query, we could not have written SELECT * FROM test1 GROUP BY x, because there is no single value for the column y that could be associated with each group. The grouped-by columns can be referenced in the select list since they have a single value in each group.

In general, if a table is grouped, columns that are not listed in GROUP BY cannot be referenced except in aggregate expressions. An example with aggregate expressions is:

```
=> SELECT x, sum(y) FROM test1 GROUP BY x;
   x  | sum
-----+-----
  a  |  4
  b  |  5
  c  |  2
```
Here *sum* is an aggregate function that computes a single value over the entire group. More information about the available aggregate functions can be found in Section 9.21.

**Tip**

Grouping without aggregate expressions effectively calculates the set of distinct values in a column. This can also be achieved using the **DISTINCT** clause (see Section 7.3.3).

Here is another example: it calculates the total sales for each product (rather than the total sales of all products):

```sql
SELECT product_id, p.name, (sum(s.units) * p.price) AS sales
FROM products p LEFT JOIN sales s USING (product_id)
GROUP BY product_id, p.name, p.price;
```

In this example, the columns `product_id`, `p.name`, and `p.price` must be in the **GROUP BY** clause since they are referenced in the query select list (but see below). The column `s.units` does not have to be in the **GROUP BY** list since it is only used in an aggregate expression (`sum(...)`), which represents the sales of a product. For each product, the query returns a summary row about all sales of the product.

If the products table is set up so that, say, `product_id` is the primary key, then it would be enough to group by `product_id` in the above example, since name and price would be **functionally dependent** on the product ID, and so there would be no ambiguity about which name and price value to return for each product ID group.

In strict SQL, **GROUP BY** can only group by columns of the source table but Postgres Pro extends this to also allow **GROUP BY** to group by columns in the select list. Grouping by value expressions instead of simple column names is also allowed.

If a table has been grouped using **GROUP BY**, but only certain groups are of interest, the **HAVING** clause can be used, much like a **WHERE** clause, to eliminate groups from the result. The syntax is:

```sql
SELECT select_list FROM ... [WHERE ...] GROUP BY ... HAVING boolean_expression
```

Expressions in the **HAVING** clause can refer both to grouped expressions and to ungrouped expressions (which necessarily involve an aggregate function).

Example:

```sql
=> SELECT x, sum(y) FROM test1 GROUP BY x HAVING sum(y) > 3;
  x  | sum
  ----+-----
    a |  4
    b |  5
  (2 rows)

=> SELECT x, sum(y) FROM test1 GROUP BY x HAVING x < 'c';
  x  | sum
  ----+-----
    a |  4
    b |  5
  (2 rows)
```

Again, a more realistic example:

```sql
SELECT product_id, p.name, (sum(s.units) * (p.price - p.cost)) AS profit
FROM products p LEFT JOIN sales s USING (product_id)
WHERE s.date > CURRENT_DATE - INTERVAL '4 weeks'
```
GROUP BY product_id, p.name, p.price, p.cost
HAVING sum(p.price * s.units) > 5000;

In the example above, the WHERE clause is selecting rows by a column that is not grouped (the expression is only true for sales during the last four weeks), while the HAVING clause restricts the output to groups with total gross sales over 5000. Note that the aggregate expressions do not necessarily need to be the same in all parts of the query.

If a query contains aggregate function calls, but no GROUP BY clause, grouping still occurs: the result is a single group row (or perhaps no rows at all, if the single row is then eliminated by HAVING). The same is true if it contains a HAVING clause, even without any aggregate function calls or GROUP BY clause.

7.2.4. GROUPING SETS, CUBE, and ROLLUP

More complex grouping operations than those described above are possible using the concept of grouping sets. The data selected by the FROM and WHERE clauses is grouped separately by each specified grouping set, aggregates computed for each group just as for simple GROUP BY clauses, and then the results returned. For example:

=> SELECT * FROM items_sold;
brand   | size | sales
-------+------+-------
Foo     | L    |  10
Foo     | M    |  20
Bar     | M    |  15
Bar     | L    |  5
(4 rows)

=> SELECT brand, size, sum(sales) FROM items_sold GROUP BY GROUPING SETS ((brand), (size), ());
brand   | size | sum
-------+------+-----
Foo     |      |  30
Bar     |      |  20
| L    |  15
| M    |  35
|      |  50
(5 rows)

Each sublist of GROUPING SETS may specify zero or more columns or expressions and is interpreted the same way as though it were directly in the GROUP BY clause. An empty grouping set means that all rows are aggregated down to a single group (which is output even if no input rows were present), as described above for the case of aggregate functions with no GROUP BY clause.

References to the grouping columns or expressions are replaced by null values in result rows for grouping sets in which those columns do not appear. To distinguish which grouping a particular output row resulted from, see Table 9.61.

A shorthand notation is provided for specifying two common types of grouping set. A clause of the form

ROLLUP ( e1, e2, e3, ... )

represents the given list of expressions and all prefixes of the list including the empty list; thus it is equivalent to

GROUPING SETS (  ( e1, e2, e3, ... ),
                 ...
                 ( e1, e2 ),
                 ( e1 ),
                 ( ) )
A clause of the form

CUBE ( e1, e2, ... )

represents the given list and all of its possible subsets (i.e., the power set). Thus

CUBE ( a, b, c )

is equivalent to

GROUPING SETS (  
  ( a, b, c ),  
  ( a, b ),  
  ( a, c ),  
  ( a ),  
  ( b, c ),  
  ( b ),  
  ( c ),  
  ( )  
)

The individual elements of a CUBE or ROLLUP clause may be either individual expressions, or sublists of elements in parentheses. In the latter case, the sublists are treated as single units for the purposes of generating the individual grouping sets. For example:

CUBE ( (a, b), (c, d) )

is equivalent to

GROUPING SETS (  
  ( a, b, c, d ),  
  ( a, b ),  
  ( c, d ),  
  ( )  
)

and

ROLLUP ( a, (b, c), d )

is equivalent to

GROUPING SETS (  
  ( a, b, c, d ),  
  ( a, b, c ),  
  ( a ),  
  ( )  
)

The CUBE and ROLLUP constructs can be used either directly in the GROUP BY clause, or nested inside a GROUPING SETS clause. If one GROUPING SETS clause is nested inside another, the effect is the same as if all the elements of the inner clause had been written directly in the outer clause.

If multiple grouping items are specified in a single GROUP BY clause, then the final list of grouping sets is the cross product of the individual items. For example:

GROUP BY a, CUBE (b, c), GROUPING SETS ((d), (e))

is equivalent to

GROUP BY GROUPING SETS (
(a, b, c, d), (a, b, c, e),
(a, b, d),   (a, b, e),
(a, c, d),   (a, c, e),
(a, d),       (a, e)
)

When specifying multiple grouping items together, the final set of grouping sets might contain duplicates. For example:

GROUP BY ROLLUP (a, b), ROLLUP (a, c)

is equivalent to

GROUP BY GROUPING SETS (  
  (a, b, c),
  (a, b),
  (a, c),
  (a),
  (a, c),
  (a),
  ()
)

If these duplicates are undesirable, they can be removed using the \texttt{DISTINCT} clause directly on the GROUP BY. Therefore:

GROUP BY \texttt{DISTINCT} ROLLUP (a, b), ROLLUP (a, c)

is equivalent to

GROUP BY GROUPING SETS (  
  (a, b, c),
  (a, b),
  (a, c),
  (a),
  ()
)

This is not the same as using \texttt{SELECT DISTINCT} because the output rows may still contain duplicates. If any of the ungrouped columns contains NULL, it will be indistinguishable from the NULL used when that same column is grouped.

\begin{mdframed}
\textbf{Note}

The construct \((a, b)\) is normally recognized in expressions as a \texttt{row constructor}. Within the \texttt{GROUP BY} clause, this does not apply at the top levels of expressions, and \((a, b)\) is parsed as a list of expressions as described above. If for some reason you \textit{need} a row constructor in a grouping expression, use \texttt{ROW(a, b)}.

\end{mdframed}

\subsection*{7.2.5. Window Function Processing}

If the query contains any window functions (see Section 3.5, Section 9.22 and Section 4.2.8), these functions are evaluated after any grouping, aggregation, and \texttt{HAVING} filtering is performed. That is, if the query uses any aggregates, \texttt{GROUP BY}, or \texttt{HAVING}, then the rows seen by the window functions are the group rows instead of the original table rows from \texttt{FROM/WHERE}.

When multiple window functions are used, all the window functions having syntactically equivalent \texttt{PARTITION BY} and \texttt{ORDER BY} clauses in their window definitions are guaranteed to be evaluated in a single pass over the data. Therefore they will see the same sort ordering, even if the \texttt{ORDER BY} does not
uniquely determine an ordering. However, no guarantees are made about the evaluation of functions having different `PARTITION BY` or `ORDER BY` specifications. (In such cases a sort step is typically required between the passes of window function evaluations, and the sort is not guaranteed to preserve ordering of rows that its `ORDER BY` sees as equivalent.)

Currently, window functions always require presorted data, and so the query output will be ordered according to one or another of the window functions’ `PARTITION BY/ORDER BY` clauses. It is not recommended to rely on this, however. Use an explicit top-level `ORDER BY` clause if you want to be sure the results are sorted in a particular way.

### 7.3. Select Lists

As shown in the previous section, the table expression in the `SELECT` command constructs an intermediate virtual table by possibly combining tables, views, eliminating rows, grouping, etc. This table is finally passed on to processing by the `select list`. The select list determines which `columns` of the intermediate table are actually output.

#### 7.3.1. Select-List Items

The simplest kind of select list is `*` which emits all columns that the table expression produces. Otherwise, a select list is a comma-separated list of value expressions (as defined in [Section 4.2](#)). For instance, it could be a list of column names:

```
SELECT a, b, c FROM ...
```

The columns names `a`, `b`, and `c` are either the actual names of the columns of tables referenced in the `FROM` clause, or the aliases given to them as explained in [Section 7.2.1.2](#). The name space available in the select list is the same as in the `WHERE` clause, unless grouping is used, in which case it is the same as in the `HAVING` clause.

If more than one table has a column of the same name, the table name must also be given, as in:

```
SELECT tbl1.a, tbl2.a, tbl1.b FROM ...
```

When working with multiple tables, it can also be useful to ask for all the columns of a particular table:

```
SELECT tbl1.*, tbl2.a FROM ...
```

See [Section 8.16.5](#) for more about the `table_name.*` notation.

If an arbitrary value expression is used in the select list, it conceptually adds a new virtual column to the returned table. The value expression is evaluated once for each result row, with the row’s values substituted for any column references. But the expressions in the select list do not have to reference any columns in the table expression of the `FROM` clause; they can be constant arithmetic expressions, for instance.

#### 7.3.2. Column Labels

The entries in the select list can be assigned names for subsequent processing, such as for use in an `ORDER BY` clause or for display by the client application. For example:

```
SELECT a AS value, b + c AS sum FROM ...
```

If no output column name is specified using `AS`, the system assigns a default column name. For simple column references, this is the name of the referenced column. For function calls, this is the name of the function. For complex expressions, the system will generate a generic name.

The `AS` key word is usually optional, but in some cases where the desired column name matches a Postgres Pro key word, you must write `AS` or double-quote the column name in order to avoid ambiguity. ([Appendix C](#) shows which key words require `AS` to be used as a column label.) For example, `FROM` is one such key word, so this does not work:

```
SELECT a from, b + c AS sum FROM ...
```
but either of these do:

```
SELECT a AS from, b + c AS sum FROM ...
SELECT a "from", b + c AS sum FROM ...
```

For greatest safety against possible future key word additions, it is recommended that you always either write AS or double-quote the output column name.

### Note

The naming of output columns here is different from that done in the FROM clause (see Section 7.2.1.2). It is possible to rename the same column twice, but the name assigned in the select list is the one that will be passed on.

#### 7.3.3. DISTINCT

After the select list has been processed, the result table can optionally be subject to the elimination of duplicate rows. The DISTINCT key word is written directly after SELECT to specify this:

```
SELECT DISTINCT select_list ...
```

(Instead of DISTINCT the key word ALL can be used to specify the default behavior of retaining all rows.)

Obviously, two rows are considered distinct if they differ in at least one column value. Null values are considered equal in this comparison.

Alternatively, an arbitrary expression can determine what rows are to be considered distinct:

```
SELECT DISTINCT ON (expression [, expression ...]) select_list ...
```

Here `expression` is an arbitrary value expression that is evaluated for all rows. A set of rows for which all the expressions are equal are considered duplicates, and only the first row of the set is kept in the output. Note that the “first row” of a set is unpredictable unless the query is sorted on enough columns to guarantee a unique ordering of the rows arriving at the DISTINCT filter. (DISTINCT ON processing occurs after ORDER BY sorting.)

The DISTINCT ON clause is not part of the SQL standard and is sometimes considered bad style because of the potentially indeterminate nature of its results. With judicious use of GROUP BY and subqueries in FROM, this construct can be avoided, but it is often the most convenient alternative.

#### 7.4. Combining Queries (UNION, INTERSECT, EXCEPT)

The results of two queries can be combined using the set operations union, intersection, and difference. The syntax is

```
query1 UNION [ALL] query2
query1 INTERSECT [ALL] query2
query1 EXCEPT [ALL] query2
```

where `query1` and `query2` are queries that can use any of the features discussed up to this point.

UNION effectively appends the result of `query2` to the result of `query1` (although there is no guarantee that this is the order in which the rows are actually returned). Furthermore, it eliminates duplicate rows from its result, in the same way as DISTINCT, unless UNION ALL is used.

INTERSECT returns all rows that are both in the result of `query1` and in the result of `query2`. Duplicate rows are eliminated unless INTERSECT ALL is used.

EXCEPT returns all rows that are in the result of `query1` but not in the result of `query2`. (This is sometimes called the difference between two queries.) Again, duplicates are eliminated unless EXCEPT ALL is used.
In order to calculate the union, intersection, or difference of two queries, the two queries must be “union compatible”, which means that they return the same number of columns and the corresponding columns have compatible data types, as described in Section 10.5.

Set operations can be combined, for example

```
query1 UNION query2 EXCEPT query3
```

which is equivalent to

```
(query1 UNION query2) EXCEPT query3
```

As shown here, you can use parentheses to control the order of evaluation. Without parentheses, **UNION** and **EXCEPT** associate left-to-right, but **INTERSECT** binds more tightly than those two operators. Thus

```
query1 UNION query2 INTERSECT query3
```

means

```
query1 UNION (query2 INTERSECT query3)
```

You can also surround an individual **query** with parentheses. This is important if the **query** needs to use any of the clauses discussed in following sections, such as **LIMIT**. Without parentheses, you’ll get a syntax error, or else the clause will be understood as applying to the output of the set operation rather than one of its inputs. For example,

```
SELECT a FROM b UNION SELECT x FROM y LIMIT 10
```

is accepted, but it means

```
(SELECT a FROM b UNION SELECT x FROM y) LIMIT 10
```

not

```
SELECT a FROM b UNION (SELECT x FROM y LIMIT 10)
```

### 7.5. Sorting Rows (**ORDER BY**)

After a query has produced an output table (after the select list has been processed) it can optionally be sorted. If sorting is not chosen, the rows will be returned in an unspecified order. The actual order in that case will depend on the scan and join plan types and the order on disk, but it must not be relied on. A particular output ordering can only be guaranteed if the sort step is explicitly chosen.

The **ORDER BY** clause specifies the sort order:

```
SELECT select_list
    FROM table_expression
    ORDER BY sort_expression1 [ASC | DESC] [NULLS { FIRST | LAST }]
        [, sort_expression2 [ASC | DESC] [NULLS { FIRST | LAST }] ...]
```

The sort expression(s) can be any expression that would be valid in the query's select list. An example is:

```
SELECT a, b FROM table1 ORDER BY a + b, c;
```

When more than one expression is specified, the later values are used to sort rows that are equal according to the earlier values. Each expression can be followed by an optional **ASC** or **DESC** keyword to set the sort direction to ascending or descending. **ASC** order is the default. Ascending order puts smaller values first, where “smaller” is defined in terms of the < operator. Similarly, descending order is determined with the > operator. ¹

The **NULLS FIRST** and **NULLS LAST** options can be used to determine whether nulls appear before or after non-null values in the sort ordering. By default, null values sort as if larger than any non-null value; that is, **NULLS FIRST** is the default for **DESC** order, and **NULLS LAST** otherwise.

Note that the ordering options are considered independently for each sort column. For example **ORDER BY x, y DESC** means **ORDER BY x ASC, y DESC**, which is not the same as **ORDER BY x DESC, y DESC**.

¹ Actually, Postgres Pro uses the *default B-tree operator class* for the expression's data type to determine the sort ordering for **ASC** and **DESC**. Conventionally, data types will be set up so that the < and > operators correspond to this sort ordering, but a user-defined data type's designer could choose to do something different.
A sort_expression can also be the column label or number of an output column, as in:

```
SELECT a + b AS sum, c FROM table1 ORDER BY sum;
SELECT a, max(b) FROM table1 GROUP BY a ORDER BY 1;
```

both of which sort by the first output column. Note that an output column name has to stand alone, that is, it cannot be used in an expression — for example, this is not correct:

```
SELECT a + b AS sum, c FROM table1 ORDER BY sum + c;          -- wrong
```

This restriction is made to reduce ambiguity. There is still ambiguity if an ORDER BY item is a simple name that could match either an output column name or a column from the table expression. The output column is used in such cases. This would only cause confusion if you use AS to rename an output column to match some other table column's name.

ORDER BY can be applied to the result of a UNION, INTERSECT, or EXCEPT combination, but in this case it is only permitted to sort by output column names or numbers, not by expressions.

### 7.6. LIMIT and OFFSET

LIMIT and OFFSET allow you to retrieve just a portion of the rows that are generated by the rest of the query:

```
SELECT select_list
FROM table_expression
[ ORDER BY ... ]
[ LIMIT { number | ALL } ] [ OFFSET number ]
```

If a limit count is given, no more than that many rows will be returned (but possibly fewer, if the query itself yields fewer rows). LIMIT ALL is the same as omitting the LIMIT clause, as is LIMIT with a NULL argument.

OFFSET says to skip that many rows before beginning to return rows. OFFSET 0 is the same as omitting the OFFSET clause, as is OFFSET with a NULL argument.

If both OFFSET and LIMIT appear, then OFFSET rows are skipped before starting to count the LIMIT rows that are returned.

When using LIMIT, it is important to use an ORDER BY clause that constrains the result rows into a unique order. Otherwise you will get an unpredictable subset of the query's rows. You might be asking for the tenth through twentieth rows, but tenth through twentieth in what ordering? The ordering is unknown, unless you specified ORDER BY.

The query optimizer takes LIMIT into account when generating query plans, so you are very likely to get different plans (yielding different row orders) depending on what you give for LIMIT and OFFSET. Thus, using different LIMIT/OFFSET values to select different subsets of a query result will give inconsistent results unless you enforce a predictable result ordering with ORDER BY. This is not a bug; it is an inherent consequence of the fact that SQL does not promise to deliver the results of a query in any particular order unless ORDER BY is used to constrain the order.

The rows skipped by an OFFSET clause still have to be computed inside the server; therefore a large OFFSET might be inefficient.

### 7.7. VALUES Lists

VALUES provides a way to generate a “constant table” that can be used in a query without having to actually create and populate a table on-disk. The syntax is

```
VALUES ( expression [, ...] ) [, ...]
```

Each parenthesized list of expressions generates a row in the table. The lists must all have the same number of elements (i.e., the number of columns in the table), and corresponding entries in each list must
have compatible data types. The actual data type assigned to each column of the result is determined using the same rules as for \texttt{UNION} (see Section 10.5).

As an example:

\texttt{VALUES (1, 'one'), (2, 'two'), (3, 'three');}

will return a table of two columns and three rows. It's effectively equivalent to:

\begin{verbatim}
SELECT 1 AS column1, 'one' AS column2
UNION ALL
SELECT 2, 'two'
UNION ALL
SELECT 3, 'three';
\end{verbatim}

By default, Postgres Pro assigns the names \texttt{column1}, \texttt{column2}, etc. to the columns of a \texttt{VALUES} table. The column names are not specified by the SQL standard and different database systems do it differently, so it's usually better to override the default names with a table alias list, like this:

\begin{verbatim}
=> SELECT * FROM (VALUES (1, 'one'), (2, 'two'), (3, 'three')) AS t (num,letter);
\end{verbatim}

\begin{verbatim}
num | letter
-----+--------
1 | one
2 | two
3 | three
\end{verbatim}

(3 rows)

Syntactically, \texttt{VALUES} followed by expression lists is treated as equivalent to:

\begin{verbatim}
SELECT select_list FROM table_expression
\end{verbatim}

and can appear anywhere a \texttt{SELECT} can. For example, you can use it as part of a \texttt{UNION}, or attach a \texttt{sort_specification} (\texttt{ORDER BY}, \texttt{LIMIT}, and/or \texttt{OFFSET}) to it. \texttt{VALUES} is most commonly used as the data source in an \texttt{INSERT} command, and next most commonly as a subquery.

For more information see \texttt{VALUES}.

### 7.8. WITH Queries (Common Table Expressions)

\texttt{WITH} provides a way to write auxiliary statements for use in a larger query. These statements, which are often referred to as Common Table Expressions or CTEs, can be thought of as defining temporary tables that exist just for one query. Each auxiliary statement in a \texttt{WITH} clause can be a \texttt{SELECT}, \texttt{INSERT}, \texttt{UPDATE}, or \texttt{DELETE}; and the \texttt{WITH} clause itself is attached to a primary statement that can also be a \texttt{SELECT}, \texttt{INSERT}, \texttt{UPDATE}, or \texttt{DELETE}.

#### 7.8.1. SELECT in WITH

The basic value of \texttt{SELECT} in \texttt{WITH} is to break down complicated queries into simpler parts. An example is:

\begin{verbatim}
WITH regional_sales AS (  
    SELECT region, SUM(amount) AS total_sales  
    FROM orders  
    GROUP BY region), top_regions AS (  
    SELECT region  
    FROM regional_sales  
    WHERE total_sales > (SELECT SUM(total_sales)/10 FROM regional_sales)
  )  
SELECT region,  
    product,  
    SUM(quantity) AS product_units,  
    SUM(amount) AS product_sales
\end{verbatim}
FROM orders
WHERE region IN (SELECT region FROM top_regions)
GROUP BY region, product;

which displays per-product sales totals in only the top sales regions. The WITH clause defines two auxiliary
statements named regional_sales and top_regions, where the output of regional_sales is used in
top_regions and the output of top_regions is used in the primary SELECT query. This example could have been written without WITH, but we’d have needed two levels of nested sub-SELECTs. It’s a bit easier
to follow this way.

### 7.8.2. Recursive Queries

The optional RECURSIVE modifier changes WITH from a mere syntactic convenience into a feature that
accomplishes things not otherwise possible in standard SQL. Using RECURSIVE, a WITH query can refer
to its own output. A very simple example is this query to sum the integers from 1 through 100:

```sql
WITH RECURSIVE t(n) AS (
    VALUES (1)
    UNION ALL
    SELECT n+1 FROM t WHERE n < 100
)
SELECT sum(n) FROM t;
```

The general form of a recursive WITH query is always a non-recursive term, then UNION (or UNION ALL),
then a recursive term, where only the recursive term can contain a reference to the query's own output.
Such a query is executed as follows:

**Recursive Query Evaluation**

1. Evaluate the non-recursive term. For UNION (but not UNION ALL), discard duplicate rows. Include all
   remaining rows in the result of the recursive query, and also place them in a temporary working table.
2. So long as the working table is not empty, repeat these steps:
   a. Evaluate the recursive term, substituting the current contents of the working table for the
      recursive self-reference. For UNION (but not UNION ALL), discard duplicate rows and rows that
duplicate any previous result row. Include all remaining rows in the result of the recursive query,
      and also place them in a temporary intermediate table.
   b. Replace the contents of the working table with the contents of the intermediate table, then empty
      the intermediate table.

**Note**

Strictly speaking, this process is iteration not recursion, but RECURSIVE is the terminology chosen
by the SQL standards committee.

In the example above, the working table has just a single row in each step, and it takes on the values
from 1 through 100 in successive steps. In the 100th step, there is no output because of the WHERE clause,
and so the query terminates.

Recursive queries are typically used to deal with hierarchical or tree-structured data. A useful example
is this query to find all the direct and indirect sub-parts of a product, given only a table that shows
immediate inclusions:

```sql
WITH RECURSIVE included_parts(sub_part, part, quantity) AS (
    SELECT sub_part, part, quantity FROM parts WHERE part = 'our_product'
    UNION ALL
    SELECT p.sub_part, p.part, p.quantity
    FROM included_parts pr, parts p
    WHERE p.part = pr.sub_part
)
```
7.8.2.1. Search Order

When computing a tree traversal using a recursive query, you might want to order the results in either depth-first or breadth-first order. This can be done by computing an ordering column alongside the other data columns and using that to sort the results at the end. Note that this does not actually control in which order the query evaluation visits the rows; that is as always in SQL implementation-dependent. This approach merely provides a convenient way to order the results afterwards.

To create a depth-first order, we compute for each result row an array of rows that we have visited so far. For example, consider the following query that searches a table tree using a link field:

```sql
WITH RECURSIVE search_tree(id, link, data, path) AS (  
    SELECT t.id, t.link, t.data, ARRAY[t.id]  
    FROM tree t  
    UNION ALL  
    SELECT t.id, t.link, t.data, path || t.id  
    FROM tree t, search_tree st  
    WHERE t.id = st.link  
  )  
SELECT * FROM search_tree  
ORDER BY path;
```

In the general case where more than one field needs to be used to identify a row, use an array of rows. For example, if we needed to track fields f1 and f2:

```sql
WITH RECURSIVE search_tree(id, link, data, path) AS (  
    SELECT t.id, t.link, t.data, ARRAY[ROW(t.f1, t.f2)]  
    FROM tree t  
    UNION ALL  
    SELECT t.id, t.link, t.data, path || ROW(t.f1, t.f2)  
    FROM tree t, search_tree st  
    WHERE t.id = st.link  
  )  
SELECT * FROM search_tree  
ORDER BY path;
```

**Tip**

Omit the `ROW()` syntax in the common case where only one field needs to be tracked. This allows a simple array rather than a composite-type array to be used, gaining efficiency.

To create a breadth-first order, you can add a column that tracks the depth of the search, for example:

```sql
WITH RECURSIVE search_tree(id, link, data, depth) AS (  
    SELECT t.id, t.link, t.data, 0  
  )
```
FROM tree t
UNION ALL
SELECT t.id, t.link, t.data, depth + 1
FROM tree t, search_tree st
WHERE t.id = st.link
)
SELECT * FROM search_tree ORDER BY depth;

To get a stable sort, add data columns as secondary sorting columns.

**Tip**

The recursive query evaluation algorithm produces its output in breadth-first search order. However, this is an implementation detail and it is perhaps unsound to rely on it. The order of the rows within each level is certainly undefined, so some explicit ordering might be desired in any case.

There is built-in syntax to compute a depth- or breadth-first sort column. For example:

```sql
WITH RECURSIVE search_tree(id, link, data) AS (
    SELECT t.id, t.link, t.data
    FROM tree t
    UNION ALL
    SELECT t.id, t.link, t.data
    FROM tree t, search_tree st
    WHERE t.id = st.link
) SEARCH DEPTH FIRST BY id SET ordercol
SELECT * FROM search_tree ORDER BY ordercol;

WITH RECURSIVE search_tree(id, link, data) AS (
    SELECT t.id, t.link, t.data
    FROM tree t
    UNION ALL
    SELECT t.id, t.link, t.data
    FROM tree t, search_tree st
    WHERE t.id = st.link
) SEARCH BREADTH FIRST BY id SET ordercol
SELECT * FROM search_tree ORDER BY ordercol;
```

This syntax is internally expanded to something similar to the above hand-written forms. The `SEARCH` clause specifies whether depth- or breadth first search is wanted, the list of columns to track for sorting, and a column name that will contain the result data that can be used for sorting. That column will implicitly be added to the output rows of the CTE.

### 7.8.2.2. Cycle Detection

When working with recursive queries it is important to be sure that the recursive part of the query will eventually return no tuples, or else the query will loop indefinitely. Sometimes, using `UNION` instead of `UNION ALL` can accomplish this by discarding rows that duplicate previous output rows. However, often a cycle does not involve output rows that are completely duplicate: it may be necessary to check just one or a few fields to see if the same point has been reached before. The standard method for handling such situations is to compute an array of the already-visited values. For example, consider again the following query that searches a table `graph` using a `link` field:

```sql
WITH RECURSIVE search_graph(id, link, data, depth) AS (
    SELECT g.id, g.link, g.data, 0
    FROM graph g
    UNION ALL
    SELECT g.id, g.link, g.data, sg.depth + 1
```
Queries

```
FROM graph g, search_graph sg
WHERE g.id = sg.link
)
SELECT * FROM search_graph;
```

This query will loop if the link relationships contain cycles. Because we require a “depth” output, just changing `UNION ALL` to `UNION` would not eliminate the looping. Instead we need to recognize whether we have reached the same row again while following a particular path of links. We add two columns `is_cycle` and `path` to the loop-prone query:

```
WITH RECURSIVE search_graph(id, link, data, depth, is_cycle, path) AS (
    SELECT g.id, g.link, g.data, 0,
    false,
    ARRAY[g.id]
    FROM graph g
    UNION ALL
    SELECT g.id, g.link, g.data, sg.depth + 1,
    g.id = ANY(path),
    path || g.id
    FROM graph g, search_graph sg
    WHERE g.id = sg.link AND NOT is_cycle
)
SELECT * FROM search_graph;
```

Aside from preventing cycles, the array value is often useful in its own right as representing the “path” taken to reach any particular row.

In the general case where more than one field needs to be checked to recognize a cycle, use an array of rows. For example, if we needed to compare fields `f1` and `f2`:

```
WITH RECURSIVE search_graph(id, link, data, depth, is_cycle, path) AS (
    SELECT g.id, g.link, g.data, 0,
    false,
    ARRAY[ROW(g.f1, g.f2)]
    FROM graph g
    UNION ALL
    SELECT g.id, g.link, g.data, sg.depth + 1,
    ROW(g.f1, g.f2) = ANY(path),
    path || ROW(g.f1, g.f2)
    FROM graph g, search_graph sg
    WHERE g.id = sg.link AND NOT is_cycle
)
SELECT * FROM search_graph;
```

Tip

Omit the `ROW()` syntax in the common case where only one field needs to be checked to recognize a cycle. This allows a simple array rather than a composite-type array to be used, gaining efficiency.

There is built-in syntax to simplify cycle detection. The above query can also be written like this:

```
WITH RECURSIVE search_graph(id, link, data, depth) AS (
    SELECT g.id, g.link, g.data, 1
    FROM graph g
    UNION ALL
    SELECT g.id, g.link, g.data, sg.depth + 1
    FROM graph g, search_graph sg
    WHERE g.id = sg.link
)
CYCLE id SET is_cycle USING path
```
Queries

SELECT * FROM search_graph;

and it will be internally rewritten to the above form. The **CYCLE** clause specifies first the list of columns to track for cycle detection, then a column name that will show whether a cycle has been detected, and finally the name of another column that will track the path. The cycle and path columns will implicitly be added to the output rows of the CTE.

### Tip

The cycle path column is computed in the same way as the depth-first ordering column shown in the previous section. A query can have both a **SEARCH** and a **CYCLE** clause, but a depth-first search specification and a cycle detection specification would create redundant computations, so it's more efficient to just use the **CYCLE** clause and order by the path column. If breadth-first ordering is wanted, then specifying both **SEARCH** and **CYCLE** can be useful.

A helpful trick for testing queries when you are not certain if they might loop is to place a **LIMIT** in the parent query. For example, this query would loop forever without the **LIMIT**:

```
WITH RECURSIVE t(n) AS {
  SELECT 1
  UNION ALL
  SELECT n+1 FROM t
}
SELECT n FROM t LIMIT 100;
```

This works because Postgres Pro's implementation evaluates only as many rows of a **WITH** query as are actually fetched by the parent query. Using this trick in production is not recommended, because other systems might work differently. Also, it usually won't work if you make the outer query sort the recursive query's results or join them to some other table, because in such cases the outer query will usually try to fetch all of the **WITH** query's output anyway.

### 7.8.3. Common Table Expression Materialization

A useful property of **WITH** queries is that they are normally evaluated only once per execution of the parent query, even if they are referred to more than once by the parent query or sibling **WITH** queries. Thus, expensive calculations that are needed in multiple places can be placed within a **WITH** query to avoid redundant work. Another possible application is to prevent unwanted multiple evaluations of functions with side-effects. However, the other side of this coin is that the optimizer is not able to push restrictions from the parent query down into a multiply-referenced **WITH** query, since that might affect all uses of the **WITH** query's output when it should affect only one. The multiply-referenced **WITH** query will be evaluated as written, without suppression of rows that the parent query might discard afterwards. (But, as mentioned above, evaluation might stop early if the reference(s) to the query demand only a limited number of rows.)

However, if a **WITH** query is non-recursive and side-effect-free (that is, it is a **SELECT** containing no volatile functions) then it can be folded into the parent query, allowing joint optimization of the two query levels. By default, this happens if the parent query references the **WITH** query just once, but not if it references the **WITH** query more than once. You can override that decision by specifying **MATERIALIZED** to force separate calculation of the **WITH** query, or by specifying **NOT MATERIALIZED** to force it to be merged into the parent query. The latter choice risks duplicate computation of the **WITH** query, but it can still give a net savings if each usage of the **WITH** query needs only a small part of the **WITH** query's full output.

A simple example of these rules is

```
WITH w AS (  
  SELECT * FROM big_table
)
SELECT * FROM w WHERE key = 123;
```

This **WITH** query will be folded, producing the same execution plan as
SELECT * FROM big_table WHERE key = 123;

In particular, if there's an index on `key`, it will probably be used to fetch just the rows having `key = 123`. On the other hand, in

WITH w AS (  
  SELECT * FROM big_table
)
SELECT * FROM w AS w1 JOIN w AS w2 ON w1.key = w2.ref
WHERE w2.key = 123;

the `WITH` query will be materialized, producing a temporary copy of `big_table` that is then joined with itself — without benefit of any index. This query will be executed much more efficiently if written as

WITH w AS NOT MATERIALIZED (  
  SELECT * FROM big_table
)
SELECT * FROM w AS w1 JOIN w AS w2 ON w1.key = w2.ref
WHERE w2.key = 123;

so that the parent query's restrictions can be applied directly to scans of `big_table`.

An example where NOT MATERIALIZED could be undesirable is

WITH w AS (  
  SELECT key, very_expensive_function(val) as f FROM some_table
)
SELECT * FROM w AS w1 JOIN w AS w2 ON w1.f = w2.f;

Here, materialization of the `WITH` query ensures that `very_expensive_function` is evaluated only once per table row, not twice.

The examples above only show `WITH` being used with `SELECT`, but it can be attached in the same way to `INSERT`, `UPDATE`, or `DELETE`. In each case it effectively provides temporary table(s) that can be referred to in the main command.

### 7.8.4. Data-Modifying Statements in `WITH`

You can use data-modifying statements (INSERT, UPDATE, or DELETE) in `WITH`. This allows you to perform several different operations in the same query. An example is:

WITH moved_rows AS (  
  DELETE FROM products  
  WHERE  
    "date" >= '2010-10-01' AND  
    "date" < '2010-11-01'  
  RETURNING *
)
INSERT INTO products_log  
SELECT * FROM moved_rows;

This query effectively moves rows from `products` to `products_log`. The DELETE in `WITH` deletes the specified rows from `products`, returning their contents by means of its RETURNING clause; and then the primary query reads that output and inserts it into `products_log`.

A fine point of the above example is that the `WITH` clause is attached to the INSERT, not the sub-SELECT within the INSERT. This is necessary because data-modifying statements are only allowed in `WITH` clauses that are attached to the top-level statement. However, normal `WITH` visibility rules apply, so it is possible to refer to the `WITH` statement's output from the sub-SELECT.

Data-modifying statements in `WITH` usually have RETURNING clauses (see Section 6.4), as shown in the example above. It is the output of the RETURNING clause, not the target table of the data-modifying statement, that forms the temporary table that can be referred to by the rest of the query. If a data-
modifying statement in WITH lacks a RETURNING clause, then it forms no temporary table and cannot be referred to in the rest of the query. Such a statement will be executed nonetheless. A not-particularly-useful example is:

```sql
WITH t AS (
    DELETE FROM foo
)
DELETE FROM bar;
```

This example would remove all rows from tables foo and bar. The number of affected rows reported to the client would only include rows removed from bar.

Recursive self-references in data-modifying statements are not allowed. In some cases it is possible to work around this limitation by referring to the output of a recursive WITH, for example:

```sql
WITH RECURSIVE included_parts(sub_part, part) AS (
    SELECT sub_part, part FROM parts WHERE part = 'our_product'
    UNION ALL
    SELECT p.sub_part, p.part
    FROM included_parts pr, parts p
    WHERE p.part = pr.sub_part
)
DELETE FROM parts
WHERE part IN (SELECT part FROM included_parts);
```

This query would remove all direct and indirect subparts of a product.

Data-modifying statements in WITH are executed exactly once, and always to completion, independently of whether the primary query reads all (or indeed any) of their output. Notice that this is different from the rule for SELECT in WITH: as stated in the previous section, execution of a SELECT is carried only as far as the primary query demands its output.

The sub-statements in WITH are executed concurrently with each other and with the main query. Therefore, when using data-modifying statements in WITH, the order in which the specified updates actually happen is unpredictable. All the statements are executed with the same snapshot (see Chapter 13), so they cannot “see” one another's effects on the target tables. This alleviates the effects of the unpredictability of the actual order of row updates, and means that RETURNING data is the only way to communicate changes between different WITH sub-statements and the main query. An example of this is that in

```sql
WITH t AS (
    UPDATE products SET price = price * 1.05
    RETURNING *
)
SELECT * FROM products;
```

the outer SELECT would return the original prices before the action of the UPDATE, while in

```sql
WITH t AS (
    UPDATE products SET price = price * 1.05
    RETURNING *
)
SELECT * FROM t;
```

the outer SELECT would return the updated data.

Trying to update the same row twice in a single statement is not supported. Only one of the modifications takes place, but it is not easy (and sometimes not possible) to reliably predict which one. This also applies to deleting a row that was already updated in the same statement: only the update is performed. Therefore you should generally avoid trying to modify a single row twice in a single statement. In particular avoid writing WITH sub-statements that could affect the same rows changed by the main statement or a sibling sub-statement. The effects of such a statement will not be predictable.
At present, any table used as the target of a data-modifying statement in `WITH` must not have a conditional rule, nor an `ALSO` rule, nor an `INSTEAD` rule that expands to multiple statements.
Chapter 8. Data Types

Postgres Pro has a rich set of native data types available to users. Users can add new types to Postgres Pro using the `CREATE TYPE` command.

Table 8.1 shows all the built-in general-purpose data types. Most of the alternative names listed in the “Aliases” column are the names used internally by Postgres Pro for historical reasons. In addition, some internally used or deprecated types are available, but are not listed here.

### Table 8.1. Data Types

<table>
<thead>
<tr>
<th>Name</th>
<th>Aliases</th>
<th>Description</th>

<td>XML data</td>
</tr>
</tbody>
</table>

### Compatibility

The following types (or spellings thereof) are specified by SQL: bigint, bit, bit varying, boolean, char, character varying, character, varchar, date, double precision, integer, interval, numeric, decimal, real, smallint, time (with or without time zone), timestamp (with or without time zone), xml.

Each data type has an external representation determined by its input and output functions. Many of the built-in types have obvious external formats. However, several types are either unique to Postgres Pro, such as geometric paths, or have several possible formats, such as the date and time types. Some of the input and output functions are not invertible, i.e., the result of an output function might lose accuracy when compared to the original input.

### 8.1. Numeric Types

Numeric types consist of two-, four-, and eight-byte integers, four- and eight-byte floating-point numbers, and selectable-precision decimals. Table 8.2 lists the available types.

#### Table 8.2. Numeric Types

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
<th>Range</th>
</tr>
</thead>
<tbody>
<tr>
<td>smallint</td>
<td>2 bytes</td>
<td>small-range integer</td>
<td>-32768 to +32767</td>
</tr>
<tr>
<td>integer</td>
<td>4 bytes</td>
<td>typical choice for integer</td>
<td>-2147483648 to +2147483647</td>
</tr>
<tr>
<td>bigint</td>

</tr>
</tbody>
</table>

The syntax of constants for the numeric types is described in Section 4.1.2. The numeric types have a full set of corresponding arithmetic operators and functions. Refer to Chapter 9 for more information. The following sections describe the types in detail.

#### 8.1.1. Integer Types

The types `smallint`, `integer`, and `bigint` store whole numbers, that is, numbers without fractional components, of various ranges. Attempts to store values outside of the allowed range will result in an error.

The type `integer` is the common choice, as it offers the best balance between range, storage size, and performance. The `smallint` type is generally only used if disk space is at a premium. The `bigint` type is designed to be used when the range of the `integer` type is insufficient.

SQL only specifies the integer types `integer` (or `int`), `smallint`, and `bigint`. The type names `int2`, `int4`, and `int8` are extensions, which are also used by some other SQL database systems.

#### 8.1.2. Arbitrary Precision Numbers

The type `numeric` can store numbers with a very large number of digits. It is especially recommended for storing monetary amounts and other quantities where exactness is required. Calculations with `numeric` values yield exact results where possible, e.g., addition, subtraction, multiplication. However, calculations on `numeric` values are very slow compared to the integer types, or to the floating-point types described in the next section.

We use the following terms below: The **precision** of a `numeric` is the total count of significant digits in the whole number; that is, the number of digits to both sides of the decimal point. The **scale** of a `numeric` is the count of decimal digits in the fractional part, to the right of the decimal point. So the number 23.5141 has a precision of 6 and a scale of 4. Integers can be considered to have a scale of zero.

Both the maximum precision and the maximum scale of a `numeric` column can be configured. To declare a column of type `numeric` use the syntax:

```sql
NUMERIC(precision, scale)
```

The precision must be positive, the scale zero or positive. Alternatively:

```sql
NUMERIC(precision)
```

selects a scale of 0. Specifying:

```sql
NUMERIC
```

without any precision or scale creates an “unconstrained numeric” column in which numeric values of any length can be stored, up to the implementation limits. A column of this kind will not coerce input values to any particular scale, whereas `numeric` columns with a declared scale will coerce input values to that scale. (The SQL standard requires a default scale of 0, i.e., coercion to integer precision. We find this a bit useless. If you're concerned about portability, always specify the precision and scale explicitly.)
Data Types

**Note**

The maximum precision that can be explicitly specified in a `NUMERIC` type declaration is 1000. An unconstrained `NUMERIC` column is subject to the limits described in Table 8.2.

If the scale of a value to be stored is greater than the declared scale of the column, the system will round the value to the specified number of fractional digits. Then, if the number of digits to the left of the decimal point exceeds the declared precision minus the declared scale, an error is raised.

Numeric values are physically stored without any extra leading or trailing zeroes. Thus, the declared precision and scale of a column are maximums, not fixed allocations. (In this sense the `numeric` type is more akin to `varchar(n)` than to `char(n)`.) The actual storage requirement is two bytes for each group of four decimal digits, plus three to eight bytes overhead.

In addition to ordinary numeric values, the `numeric` type has several special values:

- Infinity
- -Infinity
- NaN

These are adapted from the IEEE 754 standard, and represent “infinity”, “negative infinity”, and “not-a-number”, respectively. When writing these values as constants in an SQL command, you must put quotes around them, for example `UPDATE table SET x = '-Infinity'`. On input, these strings are recognized in a case-insensitive manner. The infinity values can alternatively be spelled `inf` and `-inf`.

The infinity values behave as per mathematical expectations. For example, `Infinity` plus any finite value equals `Infinity`, as does `Infinity` plus `Infinity`; but `Infinity` minus `Infinity` yields `NaN` (not a number), because it has no well-defined interpretation. Note that an infinity can only be stored in an unconstrained `numeric` column, because it notionally exceeds any finite precision limit.

The `NaN` (not a number) value is used to represent undefined calculational results. In general, any operation with a `NaN` input yields another `NaN`. The only exception is when the operation's other inputs are such that the same output would be obtained if the `NaN` were to be replaced by any finite or infinite numeric value; then, that output value is used for `NaN` too. (An example of this principle is that `NaN` raised to the zero power yields one.)

**Note**

In most implementations of the “not-a-number” concept, `NaN` is not considered equal to any other numeric value (including `NaN`). In order to allow numeric values to be sorted and used in tree-based indexes, Postgres Pro treats `NaN` values as equal, and greater than all non-`NaN` values.

The types `decimal` and `numeric` are equivalent. Both types are part of the SQL standard.

When rounding values, the `numeric` type rounds ties away from zero, while (on most machines) the `real` and `double precision` types round ties to the nearest even number. For example:

```sql
SELECT x,
    round(x::numeric) AS num_round,
    round(x::double precision) AS dbl_round
FROM generate_series(-3.5, 3.5, 1) as x;
```

<table>
<thead>
<tr>
<th>x</th>
<th>num_round</th>
<th>dbl_round</th>
</tr>
</thead>
<tbody>
<tr>
<td>-3.5</td>
<td>-4</td>
<td>-4</td>
</tr>
<tr>
<td>-2.5</td>
<td>-3</td>
<td>-2</td>
</tr>
<tr>
<td>-1.5</td>
<td>-2</td>
<td>-2</td>
</tr>
</tbody>
</table>

120
8.1.3. Floating-Point Types

The data types real and double precision are inexact, variable-precision numeric types. On all currently supported platforms, these types are implementations of IEEE Standard 754 for Binary Floating-Point Arithmetic (single and double precision, respectively), to the extent that the underlying processor, operating system, and compiler support it.

Inexact means that some values cannot be converted exactly to the internal format and are stored as approximations, so that storing and retrieving a value might show slight discrepancies. Managing these errors and how they propagate through calculations is the subject of an entire branch of mathematics and computer science and will not be discussed here, except for the following points:

- If you require exact storage and calculations (such as for monetary amounts), use the numeric type instead.
- If you want to do complicated calculations with these types for anything important, especially if you rely on certain behavior in boundary cases (infinity, underflow), you should evaluate the implementation carefully.
- Comparing two floating-point values for equality might not always work as expected.

On all currently supported platforms, the real type has a range of around 1E-37 to 1E+37 with a precision of at least 6 decimal digits. The double precision type has a range of around 1E-307 to 1E+308 with a precision of at least 15 digits. Values that are too large or too small will cause an error. Rounding might take place if the precision of an input number is too high. Numbers too close to zero that are not representable as distinct from zero will cause an underflow error.

By default, floating point values are output in text form in their shortest precise decimal representation; the decimal value produced is closer to the true stored binary value than to any other value representable in the same binary precision. (However, the output value is currently never exactly midway between two representable values, in order to avoid a widespread bug where input routines do not properly respect the round-to-nearest-even rule.) This value will use at most 17 significant decimal digits for float8 values, and at most 9 digits for float4 values.

Note

This shortest-precise output format is much faster to generate than the historical rounded format.

For compatibility with output generated by older versions of Postgres Pro, and to allow the output precision to be reduced, the extra_float_digits parameter can be used to select rounded decimal output instead. Setting a value of 0 restores the previous default of rounding the value to 6 (for float4) or 15 (for float8) significant decimal digits. Setting a negative value reduces the number of digits further; for example -2 would round output to 4 or 13 digits respectively.

Any value of extra_float_digits greater than 0 selects the shortest-precise format.

Note

Applications that wanted precise values have historically had to set extra_float_digits to 3 to obtain them. For maximum compatibility between versions, they should continue to do so.
In addition to ordinary numeric values, the floating-point types have several special values:

- Infinity
- -Infinity
- NaN

These represent the IEEE 754 special values “infinity”, “negative infinity”, and “not-a-number”, respectively. When writing these values as constants in an SQL command, you must put quotes around them, for example `UPDATE table SET x = '-Infinity'`. On input, these strings are recognized in a case-insensitive manner. The infinity values can alternatively be spelled `inf` and `-inf`.

**Note**

IEEE 754 specifies that NaN should not compare equal to any other floating-point value (including NaN). In order to allow floating-point values to be sorted and used in tree-based indexes, Postgres Pro treats NaN values as equal, and greater than all non-NaN values.

Postgres Pro also supports the SQL-standard notations `float` and `float(p)` for specifying inexact numeric types. Here, `p` specifies the minimum acceptable precision in binary digits. Postgres Pro accepts `float(1)` to `float(24)` as selecting the real type, while `float(25)` to `float(53)` select double precision. Values of `p` outside the allowed range draw an error. `float` with no precision specified is taken to mean double precision.

## 8.1.4. Serial Types

**Note**

This section describes a Postgres Pro-specific way to create an autoincrementing column. Another way is to use the SQL-standard identity column feature, described at CREATE TABLE.

The data types `smallserial`, `serial` and `bigserial` are not true types, but merely a notational convenience for creating unique identifier columns (similar to the AUTO_INCREMENT property supported by some other databases). In the current implementation, specifying:

```
CREATE TABLE tablename (  
    colname SERIAL  
);
```

is equivalent to specifying:

```
CREATE SEQUENCE tablename_colname_seq AS integer;
CREATE TABLE tablename (  
    colname integer NOT NULL DEFAULT nextval('tablename_colname_seq')  
);
ALTER SEQUENCE tablename_colname_seq OWNED BY tablename.colname;
```

Thus, we have created an integer column and arranged for its default values to be assigned from a sequence generator. A NOT NULL constraint is applied to ensure that a null value cannot be inserted. (In most cases you would also want to attach a UNIQUE or PRIMARY KEY constraint to prevent duplicate values from being inserted by accident, but this is not automatic.) Lastly, the sequence is marked as “owned by” the column, so that it will be dropped if the column or table is dropped.

**Note**

Because `smallserial`, `serial` and `bigserial` are implemented using sequences, there may be "holes" or gaps in the sequence of values which appears in the column, even if no rows are ever deleted. A value allocated from the sequence is still "used up" even if a row containing that value
is never successfully inserted into the table column. This may happen, for example, if the inserting transaction rolls back. See \nextval\() in \Section \ref{sec:nextval} for details.

To insert the next value of the sequence into the \texttt{serial} column, specify that the \texttt{serial} column should be assigned its default value. This can be done either by excluding the column from the list of columns in the \texttt{INSERT} statement, or through the use of the \texttt{DEFAULT} key word.

The type names \texttt{serial} and \texttt{serial4} are equivalent: both create integer columns. The type names \texttt{bigserial} and \texttt{serial8} work the same way, except that they create a \texttt{bigint} column. \texttt{bigserial} should be used if you anticipate the use of more than \(2^{31}\) identifiers over the lifetime of the table. The type names \texttt{smallserial} and \texttt{serial2} also work the same way, except that they create a \texttt{smallint} column.

The sequence created for a \texttt{serial} column is automatically dropped when the owning column is dropped. You can drop the sequence without dropping the column, but this will force removal of the column default expression.

\section{Monetary Types}

The \texttt{money} type stores a currency amount with a fixed fractional precision; see \Table \ref{tab:monetary}. The fractional precision is determined by the database's \texttt{lc_monetary} setting. The range shown in the table assumes there are two fractional digits. Input is accepted in a variety of formats, including integer and floating-point literals, as well as typical currency formatting, such as '$1,000.00'. Output is generally in the latter form but depends on the locale.

\begin{table}[h]
\centering
\caption{Monetary Types}
\begin{tabular}{|l|l|l|l|}
\hline
Name & Storage Size & Description & Range \\
\hline
\texttt{money} & 8 bytes & currency amount & \tt{-92233720368547758.08 to +92233720368547758.07} \\
\hline
\end{tabular}
\end{table}

Since the output of this data type is locale-sensitive, it might not work to load \texttt{money} data into a database that has a different setting of \texttt{lc_monetary}. To avoid problems, before restoring a dump into a new database make sure \texttt{lc_monetary} has the same or equivalent value as in the database that was dumped.

Values of the \texttt{numeric}, \texttt{int}, and \texttt{bigint} data types can be cast to \texttt{money}. Conversion from the \texttt{real} and \texttt{double precision} data types can be done by casting to \texttt{numeric} first, for example:

\begin{verbatim}
SELECT '12.34':float8::numeric::money;
\end{verbatim}

However, this is not recommended. Floating point numbers should not be used to handle money due to the potential for rounding errors.

A \texttt{money} value can be cast to \texttt{numeric} without loss of precision. Conversion to other types could potentially lose precision, and must also be done in two stages:

\begin{verbatim}
SELECT '52093.89':money::numeric::float8;
\end{verbatim}

Division of a \texttt{money} value by an integer value is performed with truncation of the fractional part towards zero. To get a rounded result, divide by a floating-point value, or cast the \texttt{money} value to \texttt{numeric} before dividing and back to \texttt{money} afterwards. (The latter is preferable to avoid risking precision loss.) When a \texttt{money} value is divided by another \texttt{money} value, the result is \texttt{double precision} (i.e., a pure number, not \texttt{money}); the currency units cancel each other out in the division.

\section{Character Types}

\begin{table}[h]
\centering
\caption{Character Types}
\begin{tabular}{|l|l|}
\hline
Name & Description \\
\hline
\texttt{character varying( n)}, \texttt{varchar( n)} & variable-length with limit \\
\hline
\end{tabular}
\end{table}
Table 8.4 shows the general-purpose character types available in Postgres Pro.

SQL defines two primary character types: `character varying(n)` and `character(n)`, where `n` is a positive integer. Both of these types can store strings up to `n` characters (not bytes) in length. An attempt to store a longer string into a column of these types will result in an error, unless the excess characters are all spaces, in which case the string will be truncated to the maximum length. (This somewhat bizarre exception is required by the SQL standard.) If the string to be stored is shorter than the declared length, values of type `character` will be space-padded; values of type `character varying` will simply store the shorter string.

If one explicitly casts a value to `character varying(n)` or `character(n)`, then an over-length value will be truncated to `n` characters without raising an error. (This too is required by the SQL standard.)

The notations `varchar(n)` and `char(n)` are aliases for `character varying(n)` and `character(n)`, respectively. `character` without length specifier is equivalent to `character(1)`. If `character varying` is used without length specifier, the type accepts strings of any size. The latter is a Postgres Pro extension.

In addition, Postgres Pro provides the `text` type, which stores strings of any length. Although the type `text` is not in the SQL standard, several other SQL database management systems have it as well.

Values of type `character` are physically padded with spaces to the specified width `n`, and are stored and displayed that way. However, trailing spaces are treated as semantically insignificant and disregarded when comparing two values of type `character`. In collations where whitespace is significant, this behavior can produce unexpected results; for example `SELECT 'a '::CHAR(2) collate "C" < E'a \n'::CHAR(2)` returns true, even though C locale would consider a space to be greater than a newline.

Trailing spaces are removed when converting a `character` value to one of the other string types. Note that trailing spaces are semantically significant in `character varying` and `text` values, and when using pattern matching, that is `LIKE` and regular expressions.

The characters that can be stored in any of these data types are determined by the database character set, which is selected when the database is created. Regardless of the specific character set, the character with code zero (sometimes called NUL) cannot be stored. For more information refer to Section 22.3.

The storage requirement for a short string (up to 126 bytes) is 1 byte plus the actual string, which includes the space padding in the case of `character`. Longer strings have 4 bytes of overhead instead of 1. Long strings are compressed by the system automatically, so the physical requirement on disk might be less. Very long values are also stored in background tables so that they do not interfere with rapid access to shorter column values. In any case, the longest possible character string that can be stored is about 1 GB. (The maximum value that will be allowed for `n` in the data type declaration is less than that. It wouldn’t be useful to change this because with multibyte character encodings the number of characters and bytes can be quite different. If you desire to store long strings with no specific upper limit, use `text` or `character varying` without a length specifier, rather than making up an arbitrary length limit.)

**Tip**

There is no performance difference among these three types, apart from increased storage space when using the blank-padded type, and a few extra CPU cycles to check the length when storing into a length-constrained column. While `character(n)` has performance advantages in some other database systems, there is no such advantage in Postgres Pro; in fact `character(n)` is usually the slowest of the three because of its additional storage costs. In most situations `text` or `character varying` should be used instead.
Refer to Section 4.1.2.1 for information about the syntax of string literals, and to Chapter 9 for information about available operators and functions.

**Example 8.1. Using the Character Types**

CREATE TABLE test1 (a character(4));
INSERT INTO test1 VALUES ('ok');
SELECT a, char_length(a) FROM test1; --

<table>
<thead>
<tr>
<th>a</th>
<th>char_length</th>
</tr>
</thead>
<tbody>
<tr>
<td>ok</td>
<td>2</td>
</tr>
</tbody>
</table>

CREATE TABLE test2 (b varchar(5));
INSERT INTO test2 VALUES ('ok');
INSERT INTO test2 VALUES ('good      ');
INSERT INTO test2 VALUES ('too long');
ERROR: value too long for type character varying(5)
INSERT INTO test2 VALUES ('too long'::varchar(5)); -- explicit truncation
SELECT b, char_length(b) FROM test2;

<table>
<thead>
<tr>
<th>b</th>
<th>char_length</th>
</tr>
</thead>
<tbody>
<tr>
<td>ok</td>
<td>2</td>
</tr>
<tr>
<td>good</td>
<td>5</td>
</tr>
<tr>
<td>too l</td>
<td>5</td>
</tr>
</tbody>
</table>

The **char_length** function is discussed in Section 9.4.

There are two other fixed-length character types in Postgres Pro, shown in Table 8.5. The name type exists only for the storage of identifiers in the internal system catalogs and is not intended for use by the general user. Its length is currently defined as 64 bytes (63 usable characters plus terminator) but should be referenced using the constant NAMEDATALEN in C source code. The length is set at compile time (and is therefore adjustable for special uses); the default maximum length might change in a future release. The type "char" (note the quotes) is different from char(1) in that it only uses one byte of storage. It is internally used in the system catalogs as a simplistic enumeration type.

### Table 8.5. Special Character Types

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;char&quot;</td>
<td>1 byte</td>
<td>single-byte internal type</td>
</tr>
<tr>
<td>name</td>
<td>64 bytes</td>
<td>internal type for object names</td>
</tr>
</tbody>
</table>

### 8.4. Binary Data Types

The bytea data type allows storage of binary strings; see Table 8.6.

### Table 8.6. Binary Data Types

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>bytea</td>
<td>1 or 4 bytes plus the actual binary string</td>
<td>variable-length binary string</td>
</tr>
</tbody>
</table>

A binary string is a sequence of octets (or bytes). Binary strings are distinguished from character strings in two ways. First, binary strings specifically allow storing octets of value zero and other “non-printable” octets (usually, octets outside the decimal range 32 to 126). Character strings disallow zero octets, and also disallow any other octet values and sequences of octet values that are invalid according to the database’s selected character set encoding. Second, operations on binary strings process the actual
Data Types

bytes, whereas the processing of character strings depends on locale settings. In short, binary strings are appropriate for storing data that the programmer thinks of as “raw bytes”, whereas character strings are appropriate for storing text.

The bytea type supports two formats for input and output: “hex” format and PostgreSQL’s historical “escape” format. Both of these are always accepted on input. The output format depends on the configuration parameter bytea_output; the default is hex. (Note that the hex format was introduced in PostgreSQL 9.0; earlier versions and some tools don’t understand it.)

The SQL standard defines a different binary string type, called BLOB or BINARY LARGE OBJECT. The input format is different from bytea, but the provided functions and operators are mostly the same.

8.4.1. bytea Hex Format

The “hex” format encodes binary data as 2 hexadecimal digits per byte, most significant nibble first. The entire string is preceded by the sequence \x (to distinguish it from the escape format). In some contexts, the initial backslash may need to be escaped by doubling it (see Section 4.1.2.1). For input, the hexadecimal digits can be either upper or lower case, and whitespace is permitted between digit pairs (but not within a digit pair nor in the starting \x sequence). The hex format is compatible with a wide range of external applications and protocols, and it tends to be faster to convert than the escape format, so its use is preferred.

Example:

```
SELECT '\xDEADBEEF';
```

8.4.2. bytea Escape Format

The “escape” format is the traditional Postgres Pro format for the bytea type. It takes the approach of representing a binary string as a sequence of ASCII characters, while converting those bytes that cannot be represented as an ASCII character into special escape sequences. If, from the point of view of the application, representing bytes as characters makes sense, then this representation can be convenient. But in practice it is usually confusing because it fuzzes up the distinction between binary strings and character strings, and also the particular escape mechanism that was chosen is somewhat unwieldy. Therefore, this format should probably be avoided for most new applications.

When entering bytea values in escape format, octets of certain values must be escaped, while all octet values can be escaped. In general, to escape an octet, convert it into its three-digit octal value and precede it by a backslash. Backslash itself (octet decimal value 92) can alternatively be represented by double backslashes. Table 8.7 shows the characters that must be escaped, and gives the alternative escape sequences where applicable.

<table>
<thead>
<tr>
<th>Decimal Octet Value</th>
<th>Description</th>
<th>Escaped Input Representation</th>
<th>Example</th>
<th>Hex Representation</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>zero octet</td>
<td>‘\000’</td>
<td>‘\000’::bytea</td>
<td>\x00</td>
</tr>
<tr>
<td>39</td>
<td>single quote</td>
<td>‘’’’ or ‘\047’</td>
<td>‘’’’::bytea</td>
<td>\x27</td>
</tr>
<tr>
<td>92</td>
<td>backslash</td>
<td>‘\’’ or ‘\134’</td>
<td>‘\’’::bytea</td>
<td>\x5c</td>
</tr>
<tr>
<td>0 to 31 and 127 to 255</td>
<td>“non-printable” octets</td>
<td>‘\xxx’ (octal value)</td>
<td>‘\001’::bytea</td>
<td>\x01</td>
</tr>
</tbody>
</table>

The requirement to escape non-printable octets varies depending on locale settings. In some instances you can get away with leaving them unescaped.

The reason that single quotes must be doubled, as shown in Table 8.7, is that this is true for any string literal in an SQL command. The generic string-literal parser consumes the outermost single quotes and reduces any pair of single quotes to one data character. What the bytea input function sees is just
one single quote, which it treats as a plain data character. However, the bytea input function treats backslashes as special, and the other behaviors shown in Table 8.7 are implemented by that function.

In some contexts, backslashes must be doubled compared to what is shown above, because the generic string-literal parser will also reduce pairs of backslashes to one data character; see Section 4.1.2.1.

Bytea octets are output in hex format by default. If you change bytea_output to escape, “non-printable” octets are converted to their equivalent three-digit octal value and preceded by one backslash. Most “printable” octets are output by their standard representation in the client character set, e.g.:

```
SET bytea_output = 'escape';

SELECT 'abc \153\154\155 \052\251\124'::bytea;
   bytea
--------------
  abc klm *
```

The octet with decimal value 92 (backslash) is doubled in the output. Details are in Table 8.8.

### Table 8.8. bytea Output Escaped Octets

<table>
<thead>
<tr>
<th>Decimal Octet Value</th>
<th>Description</th>
<th>Escaped Output Representation</th>
<th>Example</th>
<th>Output Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>92</td>
<td>backslash</td>
<td>\</td>
<td>'\134'::bytea</td>
<td>\</td>
</tr>
<tr>
<td>0 to 31 and 127 to 255</td>
<td>“non-printable” octets</td>
<td>\xxx (octal value)</td>
<td>'\001'::bytea</td>
<td>\001</td>
</tr>
<tr>
<td>32 to 126</td>
<td>“printable” octets</td>
<td>client character set representation</td>
<td>'\176'::bytea</td>
<td>~</td>
</tr>
</tbody>
</table>

Depending on the front end to Postgres Pro you use, you might have additional work to do in terms of escaping and unescaping bytea strings. For example, you might also have to escape line feeds and carriage returns if your interface automatically translates these.

## 8.5. Date/Time Types

Postgres Pro supports the full set of SQL date and time types, shown in Table 8.9. The operations available on these data types are described in Section 9.9. Dates are counted according to the Gregorian calendar, even in years before that calendar was introduced (see Section B.6 for more information).

### Table 8.9. Date/Time Types

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
<th>Low Value</th>
<th>High Value</th>
<th>Resolution</th>
</tr>
</thead>
<tbody>
<tr>
<td>timestamp</td>
<td>8 bytes</td>
<td>both date and time (no time zone)</td>
<td>4713 BC</td>
<td>294276 AD</td>
<td>1 microsecond</td>
</tr>
<tr>
<td>[ ( p ) ]</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>[ without time zone ]</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>timestamp [ ( p ) ] with time zone</td>
<td>8 bytes</td>
<td>both date and time, with time zone</td>
<td>4713 BC</td>
<td>294276 AD</td>
<td>1 microsecond</td>
</tr>
<tr>
<td>date</td>
<td>4 bytes</td>
<td>date (no time of day)</td>
<td>4713 BC</td>
<td>5874897 AD</td>
<td>1 day</td>
</tr>
<tr>
<td>time [ ( p ) ]</td>
<td>8 bytes</td>
<td>time of day (no date)</td>
<td>00:00:00</td>
<td>24:00:00</td>
<td>1 microsecond</td>
</tr>
<tr>
<td>[ without time zone ]</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>time [ ( p ) ]</td>
<td>12 bytes</td>
<td>time of day (no date), with time zone</td>
<td>00:00:00+1559</td>
<td>24:00:00-1559</td>
<td>1 microsecond</td>
</tr>
<tr>
<td>with time zone</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
Data Types

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
<th>Low Value</th>
<th>High Value</th>
<th>Resolution</th>
</tr>
</thead>
<tbody>
<tr>
<td>interval [</td>
<td>16 bytes</td>
<td>time interval</td>
<td>-1780000000 years</td>
<td>1780000000 years</td>
<td>1 microsecond</td>
</tr>
<tr>
<td>fields ] [ (p) ]</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Note**

The SQL standard requires that writing just `timestamp` be equivalent to `timestamp without time zone`, and Postgres Pro honors that behavior. `timestamptz` is accepted as an abbreviation for `timestamp with time zone`; this is a Postgres Pro extension.

time, timestamp, and interval accept an optional precision value `p` which specifies the number of fractional digits retained in the seconds field. By default, there is no explicit bound on precision. The allowed range of `p` is from 0 to 6.

The `interval` type has an additional option, which is to restrict the set of stored fields by writing one of these phrases:

- YEAR
- MONTH
- DAY
- HOUR
- MINUTE
- SECOND
- YEAR TO MONTH
- DAY TO HOUR
- DAY TO MINUTE
- DAY TO SECOND
- HOUR TO MINUTE
- HOUR TO SECOND
- MINUTE TO SECOND

Note that if both `fields` and `p` are specified, the `fields` must include SECOND, since the precision applies only to the seconds.

The type `time with time zone` is defined by the SQL standard, but the definition exhibits properties which lead to questionable usefulness. In most cases, a combination of `date, time, timestamp without time zone, and timestamp with time zone` should provide a complete range of date/time functionality required by any application.

### 8.5.1. Date/Time Input

Date and time input is accepted in almost any reasonable format, including ISO 8601, SQL-compatible, traditional POSTGRES, and others. For some formats, ordering of day, month, and year in date input is ambiguous and there is support for specifying the expected ordering of these fields. Set the `DateStyle` parameter to `MDY` to select month-day-year interpretation, `DMY` to select day-month-year interpretation, or `YMD` to select year-month-day interpretation.

Postgres Pro is more flexible in handling date/time input than the SQL standard requires. See Appendix B for the exact parsing rules of date/time input and for the recognized text fields including months, days of the week, and time zones.

Remember that any date or time literal input needs to be enclosed in single quotes, like text strings. Refer to Section 4.1.2.7 for more information. SQL requires the following syntax

```
type [ (p) ] 'value'
```

where `p` is an optional precision specification giving the number of fractional digits in the seconds field. Precision can be specified for `time, timestamp, and interval` types, and can range from 0 to 6. If no
precision is specified in a constant specification, it defaults to the precision of the literal value (but not more than 6 digits).

### 8.5.1.1. Dates

Table 8.10 shows some possible inputs for the date type.

**Table 8.10. Date Input**

<table>
<thead>
<tr>
<th>Example</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1999-01-08</td>
<td>ISO 8601; January 8 in any mode (recommended format)</td>
</tr>
<tr>
<td>January 8, 1999</td>
<td>unambiguous in any datestyle input mode</td>
</tr>
<tr>
<td>1/8/1999</td>
<td>January 8 in MDY mode; August 1 in DMY mode</td>
</tr>
<tr>
<td>1/18/1999</td>
<td>January 18 in MDY mode; rejected in other modes</td>
</tr>
<tr>
<td>01/02/03</td>
<td>January 2, 2003 in MDY mode; February 1, 2003 in DMY mode; February 3, 2001 in YMD mode</td>
</tr>
<tr>
<td>1999-Jan-08</td>
<td>January 8 in any mode</td>
</tr>
<tr>
<td>Jan-08-1999</td>
<td>January 8 in any mode</td>
</tr>
<tr>
<td>08-Jan-1999</td>
<td>January 8 in any mode</td>
</tr>
<tr>
<td>99-Jan-08</td>
<td>January 8 in YMD mode, else error</td>
</tr>
<tr>
<td>08-Jan-99</td>
<td>January 8, except error in YMD mode</td>
</tr>
<tr>
<td>Jan-08-99</td>
<td>January 8, except error in YMD mode</td>
</tr>
<tr>
<td>19990108</td>
<td>ISO 8601; January 8, 1999 in any mode</td>
</tr>
<tr>
<td>990108</td>
<td>ISO 8601; January 8, 1999 in any mode</td>
</tr>
<tr>
<td>1999.008</td>
<td>year and day of year</td>
</tr>
<tr>
<td>J2451187</td>
<td>Julian date</td>
</tr>
<tr>
<td>January 8, 99 BC</td>
<td>year 99 BC</td>
</tr>
</tbody>
</table>

### 8.5.1.2. Times

The time-of-day types are `time [ (p) ] without time zone` and `time [ (p) ] with time zone`. `time` alone is equivalent to `time` without time zone.

Valid input for these types consists of a time of day followed by an optional time zone. (See Table 8.11 and Table 8.12.) If a time zone is specified in the input for `time without time zone`, it is silently ignored. You can also specify a date but it will be ignored, except when you use a time zone name that involves a daylight-savings rule, such as America/New_York. In this case specifying the date is required in order to determine whether standard or daylight-savings time applies. The appropriate time zone offset is recorded in the `time with time zone` value.

**Table 8.11. Time Input**

<table>
<thead>
<tr>
<th>Example</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>04:05:06.789</td>
<td>ISO 8601</td>
</tr>
<tr>

</tr>
<tr>
<td>z</td>
<td>Short form of zulu (also in ISO 8601)</td>
</tr>
</tbody>
</table>

Refer to Section 8.5.3 for more information on how to specify time zones.

#### 8.5.1.3. Time Stamps

Valid input for the time stamp types consists of the concatenation of a date and a time, followed by an optional time zone, followed by an optional AD or BC. (Alternatively, AD/BC can appear before the time zone, but this is not the preferred ordering.) Thus:

```
1999-01-08 04:05:06
```

and:

```
1999-01-08 04:05:06 -8:00
```

are valid values, which follow the ISO 8601 standard. In addition, the common format:

```
January 8 04:05:06 1999 PST
```

is supported.

The SQL standard differentiates timestamp without time zone and timestamp with time zone literals by the presence of a “+” or “-” symbol and time zone offset after the time. Hence, according to the standard,

```
TIMESTAMP '2004-10-19 10:23:54'
```

is a timestamp without time zone, while

```
TIMESTAMP '2004-10-19 10:23:54+02'
```

is a timestamp with time zone. PostgreSQL never examines the content of a literal string before determining its type, and therefore will treat both of the above as timestamp without time zone. To ensure that a literal is treated as timestamp with time zone, give it the correct explicit type:

```
TIMESTAMP WITH TIME ZONE '2004-10-19 10:23:54+02'
```
In a literal that has been determined to be timestamp without time zone, Postgres Pro will silently ignore any time zone indication. That is, the resulting value is derived from the date/time fields in the input value, and is not adjusted for time zone.

For timestamp with time zone, the internally stored value is always in UTC (Universal Coordinated Time, traditionally known as Greenwich Mean Time, GMT). An input value that has an explicit time zone specified is converted to UTC using the appropriate offset for that time zone. If no time zone is stated in the input string, then it is assumed to be in the time zone indicated by the system's TimeZone parameter, and is converted to UTC using the offset for the timezone zone.

When a timestamp with time zone value is output, it is always converted from UTC to the current timezone zone, and displayed as local time in that zone. To see the time in another time zone, either change timezone or use the AT TIME ZONE construct (see Section 9.9.4).

Conversions between timestamp without time zone and timestamp with time zone normally assume that the timestamp without time zone value should be taken or given as timezone local time. A different time zone can be specified for the conversion using AT TIME ZONE.

8.5.1.4. Special Values

Postgres Pro supports several special date/time input values for convenience, as shown in Table 8.13. The values infinity and -infinity are specially represented inside the system and will be displayed unchanged; but the others are simply notational shorthands that will be converted to ordinary date/time values when read. (In particular, now and related strings are converted to a specific time value as soon as they are read.) All of these values need to be enclosed in single quotes when used as constants in SQL commands.

<table>
<thead>
<tr>
<th>Input String</th>
<th>Valid Types</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>epoch</td>
<td>date, timestamp</td>
<td>1970-01-01 00:00:00+00 (Unix system time zero)</td>
</tr>
<tr>
<td>infinity</td>
<td>date, timestamp</td>
<td>later than all other time stamps</td>
</tr>
<tr>
<td>-infinity</td>
<td>date, timestamp</td>
<td>earlier than all other time stamps</td>
</tr>
<tr>
<td>now</td>
<td>date, time, timestamp</td>
<td>current transaction's start time</td>
</tr>
<tr>
<td>today</td>
<td>date, timestamp</td>
<td>midnight (00:00) today</td>
</tr>
<tr>
<td>tomorrow</td>
<td>date, timestamp</td>
<td>midnight (00:00) tomorrow</td>
</tr>
<tr>
<td>yesterday</td>
<td>date, timestamp</td>
<td>midnight (00:00) yesterday</td>
</tr>
<tr>
<td>allballs</td>
<td>time</td>
<td>00:00:00.00 UTC</td>
</tr>
</tbody>
</table>

The following SQL-compatible functions can also be used to obtain the current time value for the corresponding data type: CURRENT_DATE, CURRENT_TIME, CURRENT_TIMESTAMP, LOCALTIME, LOCALTIMESTAMP. (See Section 9.9.5.) Note that these are SQL functions and are not recognized in data input strings.

Caution

While the input strings now, today, tomorrow, and yesterday are fine to use in interactive SQL commands, they can have surprising behavior when the command is saved to be executed later, for example in prepared statements, views, and function definitions. The string can be converted to a specific time value that continues to be used long after it becomes stale. Use one of the SQL functions instead in such contexts. For example, CURRENT_DATE + 1 is safer than 'tomorrow'::date.
8.5.2. Date/Time Output

The output format of the date/time types can be set to one of the four styles ISO 8601, SQL (Ingres), traditional POSTGRES (Unix date format), or German. The default is the ISO format. (The SQL standard requires the use of the ISO 8601 format. The name of the “SQL” output format is a historical accident.) Table 8.14 shows examples of each output style. The output of the date and time types is generally only the date or time part in accordance with the given examples. However, the POSTGRES style outputs date-only values in ISO format.

### Table 8.14. Date/Time Output Styles

<table>
<thead>
<tr>
<th>Style Specification</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>ISO</td>
<td>ISO 8601, SQL standard</td>
<td>1997-12-17 07:37:16-08</td>
</tr>
<tr>
<td>SQL</td>
<td>traditional style</td>
<td>12/17/1997 07:37:16.00 PST</td>
</tr>
<tr>
<td>Postgres</td>
<td>original style</td>
<td>Wed Dec 17 07:37:16 1997 PST</td>
</tr>
<tr>
<td>German</td>
<td>regional style</td>
<td>17.12.1997 07:37:16.00 PST</td>
</tr>
</tbody>
</table>

**Note**

ISO 8601 specifies the use of uppercase letter T to separate the date and time. Postgres Pro accepts that format on input, but on output it uses a space rather than T, as shown above. This is for readability and for consistency with RFC 3339 as well as some other database systems.

In the SQL and POSTGRES styles, day appears before month if DMY field ordering has been specified, otherwise month appears before day. (See Section 8.5.1 for how this setting also affects interpretation of input values.) Table 8.15 shows examples.

### Table 8.15. Date Order Conventions

<table>
<thead>
<tr>
<th>datetyle Setting</th>
<th>Input Ordering</th>
<th>Example Output</th>
</tr>
</thead>
<tbody>
<tr>
<td>SQL, DMY</td>
<td>day/month/year</td>
<td>17/12/1997 15:37:16.00 CET</td>
</tr>
<tr>
<td>SQL, MDY</td>
<td>month/day/year</td>
<td>12/17/1997 07:37:16.00 PST</td>
</tr>
<tr>
<td>Postgres, DMY</td>
<td>day/month/year</td>
<td>Wed 17 Dec 07:37:16 1997 PST</td>
</tr>
</tbody>
</table>

In the ISO style, the time zone is always shown as a signed numeric offset from UTC, with positive sign used for zones east of Greenwich. The offset will be shown as hh (hours only) if it is an integral number of hours, else as hhmm if it is an integral number of minutes, else as hh:mm:ss. (The third case is not possible with any modern time zone standard, but it can appear when working with timestamps that predate the adoption of standardized time zones.) In the other date styles, the time zone is shown as an alphabetic abbreviation if one is in common use in the current zone. Otherwise it appears as a signed numeric offset in ISO 8601 basic format (hh or hhmm).

The date/time style can be selected by the user using the SET datetyle command, the DateStyle parameter in the postgresql.conf configuration file, or the PGDATESTYLE environment variable on the server or client.

The formatting function to_char (see Section 9.8) is also available as a more flexible way to format date/time output.

8.5.3. Time Zones

Time zones, and time-zone conventions, are influenced by political decisions, not just earth geometry. Time zones around the world became somewhat standardized during the 1900s, but continue to be prone to arbitrary changes, particularly with respect to daylight-savings rules. Postgres Pro uses the widely-used IANA (Olson) time zone database for information about historical time zone rules. For times in the
future, the assumption is that the latest known rules for a given time zone will continue to be observed
indefinitely far into the future.

Postgres Pro endeavors to be compatible with the SQL standard definitions for typical usage. However,
the SQL standard has an odd mix of date and time types and capabilities. Two obvious problems are:

• Although the `date` type cannot have an associated time zone, the `time` type can. Time zones in the
  real world have little meaning unless associated with a date as well as a time, since the offset can
  vary through the year with daylight-saving time boundaries.

• The default time zone is specified as a constant numeric offset from UTC. It is therefore impossible
to adapt to daylight-saving time when doing date/time arithmetic across DST boundaries.

To address these difficulties, we recommend using date/time types that contain both date and time when
using time zones. We do not recommend using the type `time with time zone` (though it is supported by
Postgres Pro for legacy applications and for compliance with the SQL standard). Postgres Pro assumes
your local time zone for any type containing only date or time.

All timezone-aware dates and times are stored internally in UTC. They are converted to local time in the
zone specified by the `TimeZone` configuration parameter before being displayed to the client.

Postgres Pro allows you to specify time zones in three different forms:

• A full time zone name, for example `America/New_York`. The recognized time zone names are listed
  in the `pg_timezone_names` view (see Section 50.96). Postgres Pro uses the widely-used IANA time
  zone data for this purpose, so the same time zone names are also recognized by other software.

• A time zone abbreviation, for example `PST`. Such a specification merely defines a particular offset
  from UTC, in contrast to full time zone names which can imply a set of daylight savings transition
  rules as well. The recognized abbreviations are listed in the `pg_timezone_abbrevs` view (see
  Section 50.95). You cannot set the configuration parameters `TimeZone` or `log_timezone` to a time
  zone abbreviation, but you can use abbreviations in date/time input values and with the `AT TIME
  ZONE` operator.

• In addition to the timezone names and abbreviations, Postgres Pro will accept POSIX-style time
  zone specifications, as described in Section B.5. This option is not normally preferable to using a
  named time zone, but it may be necessary if no suitable IANA time zone entry is available.

In short, this is the difference between abbreviations and full names: abbreviations represent a specific
offset from UTC, whereas many of the full names imply a local daylight-savings time rule, and so have
two possible UTC offsets. As an example, 2014-06-04 12:00 America/New_York represents noon local
time in New York, which for this particular date was Eastern Daylight Time (UTC-4). So 2014-06-04
12:00 EDT specifies that same time instant. But 2014-06-04 12:00 EST specifies noon Eastern Standard
Time (UTC-5), regardless of whether daylight savings was nominally in effect on that date.

To complicate matters, some jurisdictions have used the same timezone abbreviation to mean different
UTC offsets at different times; for example, in Moscow `MSK` has meant UTC+3 in some years and UTC
+4 in others. Postgres Pro interprets such abbreviations according to whatever they meant (or had most
recently meant) on the specified date; but, as with the `EST` example above, this is not necessarily the
same as local civil time on that date.

In all cases, timezone names and abbreviations are recognized case-insensitively. (This is a change from
PostgreSQL versions prior to 8.2, which were case-sensitive in some contexts but not others.)

Neither timezone names nor abbreviations are hard-wired into the server; they are obtained from
configuration files stored under `.../share/timezone/` and `.../share/timezonesets/` of the installation
directory (see Section B.4).

The `TimeZone` configuration parameter can be set in the file `postgresql.conf`, or in any of the other
standard ways described in Chapter 18. There are also some special ways to set it:

• The SQL command `SET TIME ZONE` sets the time zone for the session. This is an alternative spelling
  of `SET TIMEZONE TO` with a more SQL-spec-compatible syntax.
• The `PGTZ` environment variable is used by libpq clients to send a `SET TIME ZONE` command to the server upon connection.

### 8.5.4. Interval Input

Interval values can be written using the following verbose syntax:

```
[@] quantity unit [quantity unit...] [direction]
```

where `quantity` is a number (possibly signed); `unit` is microsecond, millisecond, second, minute, hour, day, week, month, year, decade, century, millennium, or abbreviations or plurals of these units; `direction` can be `ago` or `empty`. The at sign (@) is optional noise. The amounts of the different units are implicitly added with appropriate sign accounting. `ago` negates all the fields. This syntax is also used for interval output, if `IntervalStyle` is set to `postgres_verbose`.

Quantities of days, hours, minutes, and seconds can be specified without explicit unit markings. For example, '1 12:59:10' is read the same as '1 day 12 hours 59 min 10 sec'. Also, a combination of years and months can be specified with a dash; for example '200-10' is read the same as '200 years 10 months'. (These shorter forms are in fact the only ones allowed by the SQL standard, and are used for output when `IntervalStyle` is set to `sql_standard`.)

Interval values can also be written as ISO 8601 time intervals, using either the “format with designators” of the standard's section 4.4.3.2 or the “alternative format” of section 4.4.3.3. The format with designators looks like this:

```
P quantity unit [ quantity unit ...] [ T [ quantity unit ...]]
```

The string must start with a `P`, and may include a `T` that introduces the time-of-day units. The available unit abbreviations are given in Table 8.16. Units may be omitted, and may be specified in any order, but units smaller than a day must appear after `T`. In particular, the meaning of `M` depends on whether it is before or after `T`.

<table>
<thead>
<tr>
<th>Abbreviation</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>Y</td>
<td>Years</td>
</tr>
<tr>
<td>M</td>
<td>Months (in the date part)</td>
</tr>
<tr>
<td>W</td>
<td>Weeks</td>
</tr>
<tr>
<td>D</td>
<td>Days</td>
</tr>
<tr>
<td>H</td>
<td>Hours</td>
</tr>
<tr>
<td>M</td>
<td>Minutes (in the time part)</td>
</tr>
<tr>
<td>S</td>
<td>Seconds</td>
</tr>
</tbody>
</table>

In the alternative format:

```
P [ years-months-days ] [ T hours:minutes:seconds ]
```

the string must begin with `P`, and a `T` separates the date and time parts of the interval. The values are given as numbers similar to ISO 8601 dates.

When writing an interval constant with a `fields` specification, or when assigning a string to an interval column that was defined with a `fields` specification, the interpretation of unmarked quantities depends on the `fields`. For example `INTERVAL '1' YEAR` is read as 1 year, whereas `INTERVAL '1'` means 1 second. Also, field values “to the right” of the least significant field allowed by the `fields` specification are silently discarded. For example, writing `INTERVAL '1 day 2:03:04' HOUR TO MINUTE` results in dropping the seconds field, but not the day field.

According to the SQL standard all fields of an interval value must have the same sign, so a leading negative sign applies to all fields; for example the negative sign in the interval literal ‘-1 2:03:04’ applies to both the days and hour/minute/second parts. Postgres Pro allows the fields to have different
signs, and traditionally treats each field in the textual representation as independently signed, so that the hour/minute/second part is considered positive in this example. If IntervalStyle is set to sql_standard then a leading sign is considered to apply to all fields (but only if no additional signs appear). Otherwise the traditional Postgres Pro interpretation is used. To avoid ambiguity, it's recommended to attach an explicit sign to each field if any field is negative.

Field values can have fractional parts: for example, '1.5 weeks' or '01:02:03.45'. However, because interval internally stores only three integer units (months, days, microseconds), fractional units must be spilled to smaller units. Fractional parts of units greater than months are truncated to be an integer number of months, e.g. '1.5 years' becomes '1 year 6 mons'. Fractional parts of weeks and days are computed to be an integer number of days and microseconds, assuming 30 days per month and 24 hours per day, e.g., '1.75 months' becomes 1 mon 22 days 12:00:00. Only seconds will ever be shown as fractional on output.

Table 8.17 shows some examples of valid interval input.

<table>
<thead>
<tr>
<th>Example</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1-2</td>
<td>SQL standard format: 1 year 2 months</td>
</tr>
<tr>
<td>3 4:05:06</td>
<td>SQL standard format: 3 days 4 hours 5 minutes 6 seconds</td>
</tr>
<tr>
<td>1 year 2 months 3 days 4 hours 5 minutes 6 seconds</td>
<td>Traditional Postgres format: 1 year 2 months 3 days 4 hours 5 minutes 6 seconds</td>
</tr>
<tr>
<td>P1Y2M3DT4H5M6S</td>
<td>ISO 8601 “format with designators”: same meaning as above</td>
</tr>
<tr>
<td>P0001-02-03T04:05:06</td>
<td>ISO 8601 “alternative format”: same meaning as above</td>
</tr>
</tbody>
</table>

Internally interval values are stored as months, days, and microseconds. This is done because the number of days in a month varies, and a day can have 23 or 25 hours if a daylight savings time adjustment is involved. The months and days fields are integers while the microseconds field can store fractional seconds. Because intervals are usually created from constant strings or timestamp subtraction, this storage method works well in most cases, but can cause unexpected results:

```sql
SELECT EXTRACT(hours from '80 minutes'::interval);
```
```
date_part
-----------
1
```

```sql
SELECT EXTRACT(days from '80 hours'::interval);
```
```
date_part
-----------
0
```

Functions justify_days and justify_hours are available for adjusting days and hours that overflow their normal ranges.

8.5.5. Interval Output

The output format of the interval type can be set to one of the four styles sql_standard, postgres, postgres_verbose, or iso_8601, using the command SET intervalstyle. The default is the postgres format. Table 8.18 shows examples of each output style.

The sql_standard style produces output that conforms to the SQL standard’s specification for interval literal strings, if the interval value meets the standard’s restrictions (either year-month only or day-time only, with no mixing of positive and negative components). Otherwise the output looks like a standard year-month literal string followed by a day-time literal string, with explicit signs added to disambiguate mixed-sign intervals.
The output of the `postgres` style matches the output of PostgreSQL releases prior to 8.4 when the `DateStyle` parameter was set to ISO.

The output of the `postgres_verbose` style matches the output of PostgreSQL releases prior to 8.4 when the `DateStyle` parameter was set to non-ISO output.

The output of the `iso_8601` style matches the “format with designators” described in section 4.4.3.2 of the ISO 8601 standard.

### Table 8.18. Interval Output Style Examples

<table>
<thead>
<tr>
<th>Style Specification</th>

</tr>
</tbody>
</table>

### 8.6. Boolean Type

Postgres Pro provides the standard SQL type `boolean`; see Table 8.19. The `boolean` type can have several states: “true”, “false”, and a third state, “unknown”, which is represented by the SQL null value.

### Table 8.19. Boolean Data Type

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>boolean</code></td>
<td>1 byte</td>
<td>state of true or false</td>
</tr>
</tbody>
</table>

Boolean constants can be represented in SQL queries by the SQL key words `TRUE`, `FALSE`, and `NULL`.

The `datatype` input function for type `boolean` accepts these string representations for the “true” state:

true
yes
on
1

and these representations for the “false” state:

false
no
off
0

Unique prefixes of these strings are also accepted, for example t or n. Leading or trailing whitespace is ignored, and case does not matter.

The `datatype` output function for type `boolean` always emits either t or f, as shown in Example 8.2.

#### Example 8.2. Using the `boolean` Type

```sql
CREATE TABLE test1 (a boolean, b text);
INSERT INTO test1 VALUES (TRUE, 'sic est');
INSERT INTO test1 VALUES (FALSE, 'non est');
SELECT * FROM test1;
```

<table>
<thead>
<tr>
<th>a</th>
<th>b</th>
</tr>
</thead>
<tbody>
<tr>
<td>t</td>
<td>sic est</td>
</tr>
</tbody>
</table>
The key words **TRUE** and **FALSE** are the preferred (SQL-compliant) method for writing Boolean constants in SQL queries. But you can also use the string representations by following the generic string-literal constant syntax described in Section 4.1.2.7, for example `'yes'::boolean`.

Note that the parser automatically understands that **TRUE** and **FALSE** are of type **boolean**, but this is not so for **NULL** because that can have any type. So in some contexts you might have to cast **NULL** to **boolean** explicitly, for example **NULL::boolean**. Conversely, the cast can be omitted from a string-literal Boolean value in contexts where the parser can deduce that the literal must be of type **boolean**.

### 8.7. Enumerated Types

Enumerated (enum) types are data types that comprise a static, ordered set of values. They are equivalent to the **enum** types supported in a number of programming languages. An example of an enum type might be the days of the week, or a set of status values for a piece of data.

#### 8.7.1. Declaration of Enumerated Types

Enum types are created using the **CREATE TYPE** command, for example:

```
CREATE TYPE mood AS ENUM ('sad', 'ok', 'happy');
```

Once created, the enum type can be used in table and function definitions much like any other type:

```
CREATE TABLE person (  
  name text,  
  current_mood mood  
);  
INSERT INTO person VALUES ('Moe', 'happy');  
SELECT * FROM person WHERE current_mood = 'happy';
```

#### 8.7.2. Ordering

The ordering of the values in an enum type is the order in which the values were listed when the type was created. All standard comparison operators and related aggregate functions are supported for enums. For example:

```
INSERT INTO person VALUES ('Larry', 'sad');  
INSERT INTO person VALUES ('Curly', 'ok');  
SELECT * FROM person WHERE current_mood > 'sad';
```

```
name | current_mood
-------+--------------
Moe   | happy
Curly | ok
(2 rows)
```

```
SELECT * FROM person WHERE current_mood > 'sad' ORDER BY current_mood;
```

```
name | current_mood
-------+--------------
Curly | ok
```
### 8.7.3. Type Safety

Each enumerated data type is separate and cannot be compared with other enumerated types. See this example:

```sql
CREATE TYPE happiness AS ENUM ('happy', 'very happy', 'ecstatic');
CREATE TABLE holidays (num_weeks integer, happiness happiness);
INSERT INTO holidays(num_weeks,happiness) VALUES (4, 'happy');
INSERT INTO holidays(num_weeks,happiness) VALUES (6, 'very happy');
INSERT INTO holidays(num_weeks,happiness) VALUES (8, 'ecstatic');
ERROR:  invalid input value for enum happiness: "sad"
SELECT person.name, holidays.num_weeks FROM person, holidays
WHERE person.current_mood = holidays.happiness;
ERROR:  operator does not exist: mood = happiness

If you really need to do something like that, you can either write a custom operator or add explicit casts to your query:

```sql
SELECT person.name, holidays.num_weeks, person.current_mood::text = holidays.happiness::text;
```

<table>
<thead>
<tr>
<th>name</th>
<th>num_weeks</th>
</tr>
</thead>
<tbody>
<tr>
<td>Moe</td>
<td>4</td>
</tr>
</tbody>
</table>

(1 row)

### 8.7.4. Implementation Details

Enum labels are case sensitive, so 'happy' is not the same as 'HAPPY'. White space in the labels is significant too.

Although enum types are primarily intended for static sets of values, there is support for adding new values to an existing enum type, and for renaming values (see `ALTER TYPE`). Existing values cannot be removed from an enum type, nor can the sort ordering of such values be changed, short of dropping and re-creating the enum type.

An enum value occupies four bytes on disk. The length of an enum value's textual label is limited by the `NAMEDATALEN` setting compiled into Postgres Pro; in standard builds this means at most 63 bytes.

The translations from internal enum values to textual labels are kept in the system catalog `pg_enum`. Querying this catalog directly can be useful.

### 8.8. Geometric Types

Geometric data types represent two-dimensional spatial objects. Table 8.20 shows the geometric types available in Postgres Pro.
### Table 8.20. Geometric Types

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
<th>Representation</th>
</tr>
</thead>
<tbody>
<tr>
<td>point</td>
<td>16 bytes</td>
<td>Point on a plane</td>
<td>(x,y)</td>
</tr>
<tr>
<td>line</td>
<td>32 bytes</td>
<td>Infinite line</td>
<td>{A,B,C}</td>
</tr>
<tr>
<td>lseg</td>
<td>32 bytes</td>
<td>Finite line segment</td>
<td>((x1,y1),(x2,y2))</td>
</tr>
<tr>
<td>box</td>
<td>32 bytes</td>
<td>Rectangular box</td>
<td>((x1,y1),(x2,y2))</td>
</tr>
<tr>
<td>path</td>
<td>16+16n bytes</td>
<td>Closed path (similar to polygon)</td>
<td>(x1,y1,...)</td>
</tr>
<tr>
<td>path</td>
<td>16+16n bytes</td>
<td>Open path</td>
<td>[(x1,y1),...]</td>
</tr>
<tr>
<td>polygon</td>
<td>40+16n bytes</td>
<td>Polygon (similar to closed path)</td>
<td>(x1,y1,..)</td>
</tr>
<tr>
<td>circle</td>
<td>24 bytes</td>
<td>Circle</td>
<td>&lt;(x,y),r&gt; (center point and radius)</td>
</tr>
</tbody>
</table>

A rich set of functions and operators is available to perform various geometric operations such as scaling, translation, rotation, and determining intersections. They are explained in Section 9.11.

### 8.8.1. Points

Points are the fundamental two-dimensional building block for geometric types. Values of type `point` are specified using either of the following syntaxes:

```
( x , y )
x , y
```

where `x` and `y` are the respective coordinates, as floating-point numbers.

Points are output using the first syntax.

### 8.8.2. Lines

Lines are represented by the linear equation \( Ax + By + C = 0 \), where \( A \) and \( B \) are not both zero. Values of type `line` are input and output in the following form:

```
{ A, B, C }
```

Alternatively, any of the following forms can be used for input:

```
[ ( x1 , y1 ) , ( x2 , y2 ) ]
( ( x1 , y1 ) , ( x2 , y2 ) )
( x1 , y1 ) , ( x2 , y2 )
    x1 , y1 ,     x2 , y2
```

where \((x1,y1)\) and \((x2,y2)\) are two different points on the line.

### 8.8.3. Line Segments

Line segments are represented by pairs of points that are the endpoints of the segment. Values of type `lseg` are specified using any of the following syntaxes:

```
[ ( x1 , y1 ) , ( x2 , y2 ) ]
( ( x1 , y1 ) , ( x2 , y2 ) )
( x1 , y1 ) , ( x2 , y2 )
    x1 , y1 ,     x2 , y2
```

where \((x1,y1)\) and \((x2,y2)\) are the end points of the line segment.

Line segments are output using the first syntax.

### 8.8.4. Boxes
8.8.5. Paths

Paths are represented by lists of connected points. Paths can be open, where the first and last points in the list are considered not connected, or closed, where the first and last points are considered connected.

Values of type path are specified using any of the following syntaxes:

\[
\begin{align*}
&[ ( x_1, y_1 ), \ldots, ( x_n, y_n ) ] \\
&( ( x_1, y_1 ), \ldots, ( x_n, y_n ) ) \\
&( x_1, y_1 ), \ldots, ( x_n, y_n ) \\
&x_1, y_1, \ldots, x_n, y_n
\end{align*}
\]

where the points are the end points of the line segments comprising the path. Square brackets \([\]) indicate an open path, while parentheses \((())\) indicate a closed path. When the outermost parentheses are omitted, as in the third through fifth syntaxes, a closed path is assumed.

Paths are output using the first or second syntax, as appropriate.

8.8.6. Polygons

Polygons are represented by lists of points (the vertexes of the polygon). Polygons are very similar to closed paths, but are stored differently and have their own set of support routines.

Values of type polygon are specified using any of the following syntaxes:

\[
\begin{align*}
&( ( x_1, y_1 ), \ldots, ( x_n, y_n ) ) \\
&( x_1, y_1 ), \ldots, ( x_n, y_n ) \\
&( x_1, y_1 ), \ldots, x_n, y_n \\
&x_1, y_1, \ldots, x_n, y_n
\end{align*}
\]

where the points are the end points of the line segments comprising the boundary of the polygon.

Polygons are output using the first syntax.

8.8.7. Circles

Circles are represented by a center point and radius. Values of type circle are specified using any of the following syntaxes:

\[
\begin{align*}
&< ( x, y ), r > \\
&( x, y ), r \\
&x, y, r \\
&x, y, r
\end{align*}
\]

where \((x,y)\) is the center point and \(r\) is the radius of the circle.

Circles are output using the first syntax.

8.9. Network Address Types
Postgres Pro offers data types to store IPv4, IPv6, and MAC addresses, as shown in Table 8.21. It is better to use these types instead of plain text types to store network addresses, because these types offer input error checking and specialized operators and functions (see Section 9.12).

### Table 8.21. Network Address Types

<table>
<thead>
<tr>
<th>Name</th>
<th>Storage Size</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>cidr</td>
<td>7 or 19 bytes</td>
<td>IPv4 and IPv6 networks</td>
</tr>
<tr>
<td>inet</td>
<td>7 or 19 bytes</td>
<td>IPv4 and IPv6 hosts and networks</td>
</tr>
<tr>
<td>macaddr</td>
<td>6 bytes</td>
<td>MAC addresses</td>
</tr>
<tr>
<td>macaddr8</td>
<td>8 bytes</td>
<td>MAC addresses (EUI-64 format)</td>
</tr>
</tbody>
</table>

When sorting `inet` or `cidr` data types, IPv4 addresses will always sort before IPv6 addresses, including IPv4 addresses encapsulated or mapped to IPv6 addresses, such as `::10.2.3.4` or `::ffff:10.4.3.2`.

#### 8.9.1. `inet`

The `inet` type holds an IPv4 or IPv6 host address, and optionally its subnet, all in one field. The subnet is represented by the number of network address bits present in the host address (the “netmask”). If the netmask is 32 and the address is IPv4, then the value does not indicate a subnet, only a single host. In IPv6, the address length is 128 bits, so 128 bits specify a unique host address. Note that if you want to accept only networks, you should use the `cidr` type rather than `inet`.

The input format for this type is `address/y` where `address` is an IPv4 or IPv6 address and `y` is the number of bits in the netmask. If the `/y` portion is omitted, the netmask is taken to be 32 for IPv4 or 128 for IPv6, so the value represents just a single host. On display, the `/y` portion is suppressed if the netmask specifies a single host.

#### 8.9.2. `cidr`

The `cidr` type holds an IPv4 or IPv6 network specification. Input and output formats follow Classless Internet Domain Routing conventions. The format for specifying networks is `address/y` where `address` is the network's lowest address represented as an IPv4 or IPv6 address, and `y` is the number of bits in the netmask. If `y` is omitted, it is calculated using assumptions from the older classful network numbering system, except it will be at least large enough to include all of the octets written in the input. It is an error to specify a network address that has bits set to the right of the specified netmask.

Table 8.22 shows some examples.

### Table 8.22. `cidr` Type Input Examples

<table>
<thead>
<tr>
<th>cidr Input</th>
<th>cidr Output</th>
<th><code>abbrev(cidr)</code></th>
</tr>
</thead>
<tbody>
<tr>
<td>192.168.100.128/25</td>
<td>192.168.100.128/25</td>
<td>192.168.100.128/25</td>
</tr>
<tr>
<td>192.168/24</td>
<td>192.168.0.0/24</td>
<td>192.168.0/24</td>
</tr>
<tr>
<td>192.168/25</td>
<td>192.168.0.0/25</td>
<td>192.168.0/25</td>
</tr>
<tr>
<td>192.168.1</td>
<td>192.168.1.0/24</td>
<td>192.168.1/24</td>
</tr>
<tr>
<td>192.168</td>
<td>192.168.0.0/24</td>
<td>192.168.0/24</td>
</tr>
<tr>
<td>128.1</td>
<td>128.1.0.0/16</td>
<td>128.1/16</td>
</tr>
<tr>
<td>128</td>
<td>128.0.0.0/16</td>
<td>128.0/16</td>
</tr>
<tr>
<td>128.1.2</td>
<td>128.1.2.0/24</td>
<td>128.1.2/24</td>
</tr>
<tr>
<td>10.1.2</td>
<td>10.1.2.0/24</td>
<td>10.1.2/24</td>
</tr>
<tr>
<td>10.1</td>
<td>10.1.0.0/16</td>
<td>10.1/16</td>
</tr>
<tr>
<td>10</td>
<td>10.0.0.0/8</td>
<td>10/8</td>
</tr>
<tr>
<td>10.1.2.3/32</td>
<td>10.1.2.3/32</td>
<td>10.1.2.3/32</td>
</tr>
</tbody>
</table>
Data Types

<table>
<thead>
<tr>
<th>cidr Input</th>
<th>cidr Output</th>
<th>abbrev( cidr)</th>
</tr>
</thead>
<tbody>
<tr>
<td>2001:4f8:3:ba::/64</td>
<td>2001:4f8:3:ba::/64</td>
<td>2001:4f8:3:ba/64</td>
</tr>
<tr>
<td>::ffff:1.2.3.0/120</td>
<td>::ffff:1.2.3.0/120</td>
<td>::ffff:1.2.3/120</td>
</tr>
<tr>
<td>::ffff:1.2.3.0/128</td>
<td>::ffff:1.2.3.0/128</td>
<td>::ffff:1.2.3/128</td>
</tr>
</tbody>
</table>

8.9.3. inet vs. cidr

The essential difference between inet and cidr data types is that inet accepts values with nonzero bits to the right of the netmask, whereas cidr does not. For example, 192.168.0.1/24 is valid for inet but not for cidr.

Tip

If you do not like the output format for inet or cidr values, try the functions host, text, and abbrev.

8.9.4. macaddr

The macaddr type stores MAC addresses, known for example from Ethernet card hardware addresses (although MAC addresses are used for other purposes as well). Input is accepted in the following formats:

'08:00:2b:01:02:03'
'08-00-2b-01-02-03'
'08002b:010203'
'08002b-010203'
'0800.2b01.0203'
'0800-2b01-0203'
'08002b010203'

These examples all specify the same address. Upper and lower case is accepted for the digits a through f. Output is always in the first of the forms shown.

IEEE Std 802-2001 specifies the second shown form (with hyphens) as the canonical form for MAC addresses, and specifies the first form (with colons) as the bit-reversed notation, so that 08-00-2b-01-02-03 = 01:00:4D:08:04:0C. This convention is widely ignored nowadays, and it is relevant only for obsolete network protocols (such as Token Ring). Postgres Pro makes no provisions for bit reversal, and all accepted formats use the canonical LSB order.

The remaining five input formats are not part of any standard.

8.9.5. macaddr8

The macaddr8 type stores MAC addresses in EUI-64 format, known for example from Ethernet card hardware addresses (although MAC addresses are used for other purposes as well). This type can accept both 6 and 8 byte length MAC addresses and stores them in 8 byte length format. MAC addresses given in 6 byte format will be stored in 8 byte length format with the 4th and 5th bytes set to FF and FE, respectively. Note that IPv6 uses a modified EUI-64 format where the 7th bit should be set to one after the conversion from EUI-48. The function macaddr8_set7bit is provided to make this change. Generally speaking, any input which is comprised of pairs of hex digits (on byte boundaries), optionally separated consistently by one of ':', '-', or '.', is accepted. The number of hex digits must be either 16 (8 bytes) or 12 (6 bytes). Leading and trailing whitespace is ignored. The following are examples of input formats that are accepted:

'08:00:2b:01:02:03:04:05'
These examples all specify the same address. Upper and lower case is accepted for the digits a through f. Output is always in the first of the forms shown.

The last six input formats shown above are not part of any standard.

To convert a traditional 48 bit MAC address in EUI-48 format to modified EUI-64 format to be included as the host portion of an IPv6 address, use `macaddr8_set7bit` as shown:

```
SELECT macaddr8_set7bit('08:00:2b:01:02:03');
```

```
  macaddr8_set7bit
-------------------------
  0a:00:2b:ff:fe:01:02:03
```

(1 row)

---

### 8.10. Bit String Types

Bit strings are strings of 1's and 0's. They can be used to store or visualize bit masks. There are two SQL bit types: `bit(n)` and `bit varying(n)`, where `n` is a positive integer.

- `bit` type data must match the length `n` exactly; it is an error to attempt to store shorter or longer bit strings. `bit varying` data is of variable length up to the maximum length `n`; longer strings will be rejected. Writing `bit` without a length is equivalent to `bit(1)`, while `bit varying` without a length specification means unlimited length.

**Note**

If one explicitly casts a bit-string value to `bit(n)`, it will be truncated or zero-padded on the right to be exactly `n` bits, without raising an error. Similarly, if one explicitly casts a bit-string value to `bit varying(n)`, it will be truncated on the right if it is more than `n` bits.

Refer to [Section 4.1.2.5](#) for information about the syntax of bit string constants. Bit-logical operators and string manipulation functions are available; see [Section 9.6](#).

**Example 8.3. Using the Bit String Types**

```
CREATE TABLE test (a BIT(3), b BIT VARYING(5));
INSERT INTO test VALUES (B'101', B'00');
INSERT INTO test VALUES (B'10', B'101');
```

```
ERROR:  bit string length 2 does not match type bit(3)
```

```
INSERT INTO test VALUES (B'10'::bit(3), B'101');
SELECT * FROM test;
```

```
a | b
---
101 | 00
100 | 101
```
A bit string value requires 1 byte for each group of 8 bits, plus 5 or 8 bytes overhead depending on the length of the string (but long values may be compressed or moved out-of-line, as explained in Section 8.3 for character strings).

### 8.11. Text Search Types

Postgres Pro provides two data types that are designed to support full text search, which is the activity of searching through a collection of natural-language documents to locate those that best match a query. The `tsvector` type represents a document in a form optimized for text search; the `tsquery` type similarly represents a text query. Chapter 12 provides a detailed explanation of this facility, and Section 9.13 summarizes the related functions and operators.

#### 8.11.1. tsvector

A `tsvector` value is a sorted list of distinct lexemes, which are words that have been normalized to merge different variants of the same word (see Chapter 12 for details). Sorting and duplicate-elimination are done automatically during input, as shown in this example:

```
SELECT 'a fat cat sat on a mat and ate a fat rat'::tsvector;
```

```
'\'a\' 'and' 'ate' 'cat' 'fat' 'mat' 'on' 'rat' 'sat'
```

To represent lexemes containing whitespace or punctuation, surround them with quotes:

```
SELECT $$the lexeme '    ' contains spaces$$::tsvector;
```

```
-------------------------------------------
'    ' 'contains' 'lexeme' 'spaces' 'the'
```

(We use dollar-quoted string literals in this example and the next one to avoid the confusion of having to double quote marks within the literals.) Embedded quotes and backslashes must be doubled:

```
SELECT $$the lexeme 'Joe''s' contains a quote$$::tsvector;
```

```
------------------------------------------------
'Joe''s' 'a' 'contains' 'lexeme' 'quote' 'the'
```

Optionally, integer positions can be attached to lexemes:

```
SELECT 'a:1 fat:2 cat:3 sat:4 on:5 a:6 mat:7 and:8 ate:9 a:10 fat:11 rat:12'::tsvector;
```

```
-------------------------------------------------------------------------------
'a':1,6,10 'and':8 'ate':9 'cat':3 'fat':2,11 'mat':7 'on':5 'rat':12 'sat':4
```

A position normally indicates the source word's location in the document. Positional information can be used for proximity ranking. Position values can range from 1 to 16383; larger numbers are silently set to 16383. Duplicate positions for the same lexeme are discarded.

Lexemes that have positions can further be labeled with a weight, which can be A, B, C, or D. D is the default and hence is not shown on output:

```
SELECT 'a:1A fat:2B,4C cat:5D'::tsvector;
```

```
------------------------
'a':1A 'cat':5 'fat':2B,4C
```

Weights are typically used to reflect document structure, for example by marking title words differently from body words. Text search ranking functions can assign different priorities to the different weight markers.

It is important to understand that the `tsvector` type itself does not perform any word normalization; it assumes the words it is given are normalized appropriately for the application. For example,

```
SELECT 'The Fat Rats'::tsvector;
```
Data Types

---

For most English-text-searching applications the above words would be considered non-normalized, but `tsvector` doesn’t care. Raw document text should usually be passed through `to_tsvector` to normalize the words appropriately for searching:

```sql
SELECT to_tsvector('english', 'The Fat Rats');
```

Again, see Chapter 12 for more detail.

### 8.11.2. tsquery

A `tsquery` value stores lexemes that are to be searched for, and can combine them using the Boolean operators & (AND), | (OR), and ! (NOT), as well as the phrase search operator <-> (FOLLOWED BY). There is also a variant <N> of the FOLLOWED BY operator, where N is an integer constant that specifies the distance between the two lexemes being searched for. <-> is equivalent to <1>.

Parentheses can be used to enforce grouping of these operators. In the absence of parentheses, ! (NOT) binds most tightly, <-> (FOLLOWED BY) next most tightly, then & (AND), with | (OR) binding the least tightly.

Here are some examples:

```sql
SELECT 'fat & rat'::tsquery;
```

```sql
SELECT 'fat & (rat | cat)'::tsquery;
```

```sql
SELECT 'fat & rat & ! cat'::tsquery;
```

Optionally, lexemes in a `tsquery` can be labeled with one or more weight letters, which restricts them to match only `tsvector` lexemes with one of those weights:

```sql
SELECT 'fat:ab & cat'::tsquery;
```

Also, lexemes in a `tsquery` can be labeled with * to specify prefix matching:

```sql
SELECT 'super:*'::tsquery;
```

This query will match any word in a `tsvector` that begins with “super”.

Quoting rules for lexemes are the same as described previously for lexemes in `tsvector`; and, as with `tsvector`, any required normalization of words must be done before converting to the `tsquery` type. The `to_tsquery` function is convenient for performing such normalization:
SELECT to_tsquery('Fat:ab & Cats');

   to_tsquery
----------
fat':AB & 'cat'

Note that `to_tsquery` will process prefixes in the same way as other words, which means this comparison returns true:

SELECT to_tsvector( 'postgraduate' ) @@ to_tsquery( 'postgres:*' );

?column?
---------
t

because `postgres` gets stemmed to `postgr`:

SELECT to_tsvector( 'postgraduate' ), to_tsquery( 'postgres:*' );

   to_tsvector | to_tsquery
---------------+------------
postgradu':1 | 'postgr':*

which will match the stemmed form of `postgraduate`.

8.12. UUID Type

The data type `uuid` stores Universally Unique Identifiers (UUID) as defined by RFC 4122, ISO/IEC 9834-8:2005, and related standards. (Some systems refer to this data type as a globally unique identifier, or GUID, instead.) This identifier is a 128-bit quantity that is generated by an algorithm chosen to make it very unlikely that the same identifier will be generated by anyone else in the known universe using the same algorithm. Therefore, for distributed systems, these identifiers provide a better uniqueness guarantee than sequence generators, which are only unique within a single database.

A UUID is written as a sequence of lower-case hexadecimal digits, in several groups separated by hyphens, specifically a group of 8 digits followed by three groups of 4 digits followed by a group of 12 digits, for a total of 32 digits representing the 128 bits. An example of a UUID in this standard form is:

```
a0eebc99-9c0b-4ef8-bb6d-6bb9bd380a11
```

Postgres Pro also accepts the following alternative forms for input: use of upper-case digits, the standard format surrounded by braces, omitting some or all hyphens, adding a hyphen after any group of four digits. Examples are:

```
A0EEBC99-9C0B-4EF8-BB6D-6BB9BD380A11
{a0eebc99-9c0b-4ef8-bb6d-6bb9bd380a11}
a0eebc99c0b4ef8bb6d6bb9bd380a11
a0ee-bc99-9c0b-4ef8-bb6d-6bb9-bd38-0a11
{a0eebc99-9c0b4ef8-bb6d6bb9-bd380a11}
```

Output is always in the standard form.

See Section 9.14 for how to generate a UUID in PostgreSQL.

8.13. XML Type

The `xml` data type can be used to store XML data. Its advantage over storing XML data in a `text` field is that it checks the input values for well-formedness, and there are support functions to perform type-safe operations on it; see Section 9.15. Use of this data type requires the installation to have been built with `configure --with-libxml`.

The `xml` type can store well-formed “documents”, as defined by the XML standard, as well as “content” fragments, which are defined by reference to the more permissive “document node” of the XQuery and XPath data model. Roughly, this means that content fragments can have more than one top-level element or character node. The expression `xmlvalue IS DOCUMENT` can be used to evaluate whether a particular `xml` value is a full document or only a content fragment.
Limits and compatibility notes for the xml data type can be found in Section D.3.

8.13.1. Creating XML Values

To produce a value of type xml from character data, use the function xmlparse:

```sql
XMLPARSE ( { DOCUMENT | CONTENT } value)
```

**Examples:**

```sql
XMLPARSE (DOCUMENT '<?xml version="1.0"?><book><title>Manual</title><chapter>...</chapter></book>')</nXMLPARSE (CONTENT 'abc<foo>bar</foo><bar>foo</bar>')
```

While this is the only way to convert character strings into XML values according to the SQL standard, the Postgres Pro-specific syntaxes:

```sql
xml '<foo>bar</foo>'
'<foo>bar</foo>':::xml
```

can also be used.

The xml type does not validate input values against a document type declaration (DTD), even when the input value specifies a DTD. There is also currently no built-in support for validating against other XML schema languages such as XML Schema.

The inverse operation, producing a character string value from xml, uses the function xmlserialize:

```sql
XMLSERIALIZE ( { DOCUMENT | CONTENT } value AS type )
```

type can be character, character varying, or text (or an alias for one of those). Again, according to the SQL standard, this is the only way to convert between type xml and character types, but Postgres Pro also allows you to simply cast the value.

When a character string value is cast to or from type xml without going through XMLPARSE or XMLSERIALIZE, respectively, the choice of DOCUMENT versus CONTENT is determined by the “XML option” session configuration parameter, which can be set using the standard command:

```sql
SET XML OPTION ( DOCUMENT | CONTENT );
```

or the more Postgres Pro-like syntax

```sql
SET xmloption TO ( DOCUMENT | CONTENT );
```

The default is CONTENT, so all forms of XML data are allowed.

8.13.2. Encoding Handling

Care must be taken when dealing with multiple character encodings on the client, server, and in the XML data passed through them. When using the text mode to pass queries to the server and query results to the client (which is the normal mode), Postgres Pro converts all character data passed between the client and the server and vice versa to the character encoding of the respective end; see Section 22.3. This includes string representations of XML values, such as in the above examples. This would ordinarily mean that encoding declarations contained in XML data can become invalid as the character data is converted to other encodings while traveling between client and server, because the embedded encoding declaration is not changed. To cope with this behavior, encoding declarations contained in character strings presented for input to the xml type are ignored, and content is assumed to be in the current server encoding. Consequently, for correct processing, character strings of XML data must be sent from the client in the current client encoding. It is the responsibility of the client to either convert documents to the current client encoding before sending them to the server, or to adjust the client encoding appropriately. On output, values of type xml will not have an encoding declaration, and clients should assume all data is in the current client encoding.

When using binary mode to pass query parameters to the server and query results back to the client, no encoding conversion is performed, so the situation is different. In this case, an encoding declaration in
the XML data will be observed, and if it is absent, the data will be assumed to be in UTF-8 (as required by the XML standard; note that Postgres Pro does not support UTF-16). On output, data will have an encoding declaration specifying the client encoding, unless the client encoding is UTF-8, in which case it will be omitted.

Needless to say, processing XML data with Postgres Pro will be less error-prone and more efficient if the XML data encoding, client encoding, and server encoding are the same. Since XML data is internally processed in UTF-8, computations will be most efficient if the server encoding is also UTF-8.

Caution

Some XML-related functions may not work at all on non-ASCII data when the server encoding is not UTF-8. This is known to be an issue for `xmltable()` and `xpath()` in particular.

8.13.3. Accessing XML Values

The `xml` data type is unusual in that it does not provide any comparison operators. This is because there is no well-defined and universally useful comparison algorithm for XML data. One consequence of this is that you cannot retrieve rows by comparing an `xml` column against a search value. XML values should therefore typically be accompanied by a separate key field such as an ID. An alternative solution for comparing XML values is to convert them to character strings first, but note that character string comparison has little to do with a useful XML comparison method.

Since there are no comparison operators for the `xml` data type, it is not possible to create an index directly on a column of this type. If speedy searches in XML data are desired, possible workarounds include casting the expression to a character string type and indexing that, or indexing an XPath expression. Of course, the actual query would have to be adjusted to search by the indexed expression.

The text-search functionality in Postgres Pro can also be used to speed up full-document searches of XML data. The necessary preprocessing support is, however, not yet available in the Postgres Pro distribution.

8.14. JSON Types

JSON data types are for storing JSON (JavaScript Object Notation) data, as specified in RFC 7159. Such data can also be stored as `text`, but the JSON data types have the advantage of enforcing that each stored value is valid according to the JSON rules. There are also assorted JSON-specific functions and operators available for data stored in these data types; see Section 9.16.

Postgres Pro offers two types for storing JSON data: `json` and `jsonb`. To implement efficient query mechanisms for these data types, Postgres Pro also provides the `jsonpath` data type described in Section 8.14.7.

The `json` and `jsonb` data types accept almost identical sets of values as input. The major practical difference is one of efficiency. The `json` data type stores an exact copy of the input text, which processing functions must reparse on each execution; while `jsonb` data is stored in a decomposed binary format that makes it slightly slower to input due to added conversion overhead, but significantly faster to process, since no reparsing is needed. `jsonb` also supports indexing, which can be a significant advantage.

Because the `json` type stores an exact copy of the input text, it will preserve semantically-insignificant white space between tokens, as well as the order of keys within JSON objects. Also, if a JSON object within the value contains the same key more than once, all the key/value pairs are kept. (The processing functions consider the last value as the operative one.) By contrast, `jsonb` does not preserve white space, does not preserve the order of object keys, and does not keep duplicate object keys. If duplicate keys are specified in the input, only the last value is kept.

In general, most applications should prefer to store JSON data as `jsonb`, unless there are quite specialized needs, such as legacy assumptions about ordering of object keys.
RFC 7159 specifies that JSON strings should be encoded in UTF8. It is therefore not possible for the JSON types to conform rigidly to the JSON specification unless the database encoding is UTF8. Attempts to directly include characters that cannot be represented in the database encoding will fail; conversely, characters that can be represented in the database encoding but not in UTF8 will be allowed.

RFC 7159 permits JSON strings to contain Unicode escape sequences denoted by \uXXXX. In the input function for the json type, Unicode escapes are allowed regardless of the database encoding, and are checked only for syntactic correctness (that is, that four hex digits follow \u). However, the input function for jsonb is stricter: it disallows Unicode escapes for characters that cannot be represented in the database encoding. The json type also rejects \u0000 (because that cannot be represented in Postgres Pro’s text type), and it insists that any use of Unicode surrogate pairs to designate characters outside the Unicode Basic Multilingual Plane be correct. Valid Unicode escapes are converted to the equivalent single character for storage; this includes folding surrogate pairs into a single character.

Many of the JSON processing functions described in Section 9.16 will convert Unicode escapes to regular characters, and will therefore throw the same types of errors just described even if their input is of type json not jsonb. The fact that the json input function does not make these checks may be considered a historical artifact, although it does allow for simple storage (without processing) of JSON Unicode escapes in a database encoding that does not support the represented characters.

When converting textual JSON input into jsonb, the primitive types described by RFC 7159 are effectively mapped onto native Postgres Pro types, as shown in Table 8.23. Therefore, there are some minor additional constraints on what constitutes valid jsonb data that do not apply to the json type, nor to JSON in the abstract, corresponding to limits on what can be represented by the underlying data type. Notably, jsonb will reject numbers that are outside the range of the Postgres Pro numeric data type, while json will not. Such implementation-defined restrictions are permitted by RFC 7159. However, in practice such problems are far more likely to occur in other implementations, as it is common to represent JSON’s number primitive type as IEEE 754 double precision floating point (which RFC 7159 explicitly anticipates and allows for). When using JSON as an interchange format with such systems, the danger of losing numeric precision compared to data originally stored by Postgres Pro should be considered.

Conversely, as noted in the table there are some minor restrictions on the input format of JSON primitive types that do not apply to the corresponding Postgres Pro types.

<table>
<thead>

<td>SQL NULL is a different concept</td>
</tr>
</tbody>
</table>

8.14.1. JSON Input and Output Syntax

The input/output syntax for the JSON data types is as specified in RFC 7159.

The following are all valid json (or jsonb) expressions:

-- Simple scalar/primitive value
-- Primitive values can be numbers, quoted strings, true, false, or null
SELECT '5'::json;

-- Array of zero or more elements (elements need not be of same type)
SELECT '[1, 2, "foo", null]'::json;

-- Object containing pairs of keys and values
-- Note that object keys must always be quoted strings
SELECT '{"bar": "baz", "balance": 7.77, "active": false}'::json;

-- Arrays and objects can be nested arbitrarily
SELECT '{"foo": [true, "bar"], "tags": {"a": 1, "b": null}}'::json;

As previously stated, when a JSON value is input and then printed without any additional processing, json outputs the same text that was input, while jsonb does not preserve semantically-insignificant details such as whitespace. For example, note the differences here:

SELECT '{"bar": "baz", "balance": 7.77, "active":false}'::json;
-------------------------------------------------
{"bar": "baz", "balance": 7.77, "active":false}
(1 row)

SELECT '{"bar": "baz", "balance": 7.77, "active":false}'::jsonb;
--------------------------------------------------
{"bar": "baz", "active": false, "balance": 7.77}
(1 row)

One semantically-insignificant detail worth noting is that in jsonb, numbers will be printed according to the behavior of the underlying numeric type. In practice this means that numbers entered with E notation will be printed without it, for example:

SELECT '{"reading": 1.230e-5}'::json, '{"reading": 1.230e-5}'::jsonb;
json          |          jsonb
-----------------------+-------------------------
{"reading": 1.230e-5} | {"reading": 0.00001230}
(1 row)

However, jsonb will preserve trailing fractional zeroes, as seen in this example, even though those are semantically insignificant for purposes such as equality checks.

For the list of built-in functions and operators available for constructing and processing JSON values, see Section 9.16.

8.14.2. Designing JSON Documents

Representing data as JSON can be considerably more flexible than the traditional relational data model, which is compelling in environments where requirements are fluid. It is quite possible for both approaches to co-exist and complement each other within the same application. However, even for applications where maximal flexibility is desired, it is still recommended that JSON documents have a somewhat fixed structure. The structure is typically unenforced (though enforcing some business rules declaratively is possible), but having a predictable structure makes it easier to write queries that usefully summarize a set of “documents” (datums) in a table.

JSON data is subject to the same concurrency-control considerations as any other data type when stored in a table. Although storing large documents is practicable, keep in mind that any update acquires a row-level lock on the whole row. Consider limiting JSON documents to a manageable size in order to decrease lock contention among updating transactions. Ideally, JSON documents should each represent an atomic datum that business rules dictate cannot reasonably be further subdivided into smaller datums that could be modified independently.
8.14.3. jsonb Containment and Existence

Testing containment is an important capability of jsonb. There is no parallel set of facilities for the json type. Containment tests whether one jsonb document has contained within it another one. These examples return true except as noted:

-- Simple scalar/primitive values contain only the identical value:
SELECT "foo"::jsonb @> "foo"::jsonb;

-- The array on the right side is contained within the one on the left:
SELECT '[1, 2, 3]'::jsonb @> '[1, 3]'::jsonb;

-- Order of array elements is not significant, so this is also true:
SELECT '[1, 2, 3]'::jsonb @> '[3, 1]'::jsonb;

-- Duplicate array elements don't matter either:
SELECT '[1, 2, 3]'::jsonb @> '[1, 2, 2]'::jsonb;

-- The object with a single pair on the right side is contained
-- within the object on the left side:
SELECT '{"product": "PostgreSQL", "version": 9.4, "jsonb": true}'::jsonb @> '{"version": 9.4}'::jsonb;

-- The array on the right side is not considered contained within the
-- array on the left, even though a similar array is nested within it:
SELECT '[1, 2, [1, 3]]'::jsonb @> '[1, 3]'::jsonb; -- yields false

-- But with a layer of nesting, it is contained:
SELECT '[1, 2, [1, 3]]'::jsonb @> '[[1, 3]]'::jsonb;

-- Similarly, containment is not reported here:
SELECT '{"foo": {"bar": "baz"}}'::jsonb @> '{"bar": "baz"}'::jsonb; -- yields false

-- A top-level key and an empty object is contained:
SELECT '{"foo": {"bar": "baz"}}'::jsonb @> '{"foo": {}}'::jsonb;

The general principle is that the contained object must match the containing object as to structure and data contents, possibly after discarding some non-matching array elements or object key/value pairs from the containing object. But remember that the order of array elements is not significant when doing a containment match, and duplicate array elements are effectively considered only once.

As a special exception to the general principle that the structures must match, an array may contain a primitive value:

-- This array contains the primitive string value:
SELECT '{"foo", "bar"}'::jsonb @> '"bar"'::jsonb;

-- This exception is not reciprocal -- non-containment is reported here:
SELECT '"bar"'::jsonb @> '{"bar"}'::jsonb; -- yields false

jsonb also has an existence operator, which is a variation on the theme of containment: it tests whether a string (given as a text value) appears as an object key or array element at the top level of the jsonb value. These examples return true except as noted:

-- String exists as array element:
SELECT '{"foo", "bar", "baz"]'::jsonb ? 'bar';

-- String exists as object key:
SELECT '{"foo": "bar"]'::jsonb ? 'foo';
-- Object values are not considered:
SELECT '{"foo": "bar"} '::jsonb ? 'bar'; -- yields false

-- As with containment, existence must match at the top level:
SELECT '{"foo": {"bar": "baz"}} '::jsonb ? 'bar'; -- yields false

-- A string is considered to exist if it matches a primitive JSON string:
SELECT '"foo" '::jsonb ? 'foo';

JSON objects are better suited than arrays for testing containment or existence when there are many keys or elements involved, because unlike arrays they are internally optimized for searching, and do not need to be searched linearly.

Tip

Because JSON containment is nested, an appropriate query can skip explicit selection of sub-objects. As an example, suppose that we have a doc column containing objects at the top level, with most objects containing tags fields that contain arrays of sub-objects. This query finds entries in which sub-objects containing both "term": "paris" and "term": "food" appear, while ignoring any such keys outside the tags array:

SELECT doc->'site_name' FROM websites
   WHERE doc @> '{"tags":[{"term": "paris"}, {"term": "food"}]}';

One could accomplish the same thing with, say,

SELECT doc->'site_name' FROM websites
   WHERE doc->'tags' @> '{"term": "paris"}, {"term": "food"}';

but that approach is less flexible, and often less efficient as well.

On the other hand, the JSON existence operator is not nested: it will only look for the specified key or array element at top level of the JSON value.

The various containment and existence operators, along with all other JSON operators and functions are documented in Section 9.16.

8.14.4. jsonb Indexing

GIN indexes can be used to efficiently search for keys or key/value pairs occurring within a large number of jsonb documents (datums). Two GIN "operator classes" are provided, offering different performance and flexibility trade-offs.

The default GIN operator class for jsonb supports queries with top-level key-exists operators ?, ?& and ?| operators and path/value-exists operator @>. (For details of the semantics that these operators implement, see Table 9.45.) An example of creating an index with this operator class is:

CREATE INDEX idxgin ON api USING GIN (jdoc);

The non-default GIN operator class jsonb_path_ops supports indexing the @> operator only. An example of creating an index with this operator class is:

CREATE INDEX idxginp ON api USING GIN (jdoc jsonb_path_ops);

Consider the example of a table that stores JSON documents retrieved from a third-party web service, with a documented schema definition. A typical document is:

```json
{
    "guid": "9c36adc1-7fb5-4d5b-83b4-90356a46061a",
    "name": "Angela Barton",
    "is_active": true,
    "company": "Magnafone",
}```
Data Types

"address": "178 Howard Place, Gulf, Washington, 702",
"registered": "2009-11-07T08:53:22 +08:00",
"latitude": 19.793713,
"longitude": 86.513373,
"tags": [
  "enim",
  "aliquip",
  "qui"
]
}

We store these documents in a table named api, in a jsonb column named jdoc. If a GIN index is created on this column, queries like the following can make use of the index:

-- Find documents in which the key "company" has value "Magnafone"
SELECT jdoc->'guid', jdoc->'name' FROM api WHERE jdoc @> '{"company": "Magnafone"}';

However, the index could not be used for queries like the following, because though the operator ? is indexable, it is not applied directly to the indexed column jdoc:

-- Find documents in which the key "tags" contains key or array element "qui"
SELECT jdoc->'guid', jdoc->'name' FROM api WHERE jdoc -> 'tags' ? 'qui';

Still, with appropriate use of expression indexes, the above query can use an index. If querying for particular items within the "tags" key is common, defining an index like this may be worthwhile:

CREATE INDEX idxgintags ON api USING GIN ((jdoc -> 'tags'));

Now, the WHERE clause jdoc -> 'tags' ? 'qui' will be recognized as an application of the indexable operator ? to the indexed expression jdoc -> 'tags'. (More information on expression indexes can be found in Section 11.7.)

Also, GIN index supports @@ and @? operators, which perform jsonpath matching.

SELECT jdoc->'guid', jdoc->'name' FROM api WHERE jdoc @@ '$.tags[*] == "qui"';
SELECT jdoc->'guid', jdoc->'name' FROM api WHERE jdoc @? '$.tags[*] ? (@ == "qui")';

GIN index extracts statements of following form out of jsonpath: accessor_chain = const. Accessors chain may consist of .key, [*], and [index] accessors. jsonb_ops additionally supports .* and .** accessors.

Another approach to querying is to exploit containment, for example:

-- Find documents in which the key "tags" contains array element "qui"
SELECT jdoc->'guid', jdoc->'name' FROM api WHERE jdoc @> '{"tags": ["qui"]}';

A simple GIN index on the jdoc column can support this query. But note that such an index will store copies of every key and value in the jdoc column, whereas the expression index of the previous example stores only data found under the tags key. While the simple-index approach is far more flexible (since it supports queries about any key), targeted expression indexes are likely to be smaller and faster to search than a simple index.

Although the jsonb_path_ops operator class supports only queries with the @>, @@ and @? operators, it has notable performance advantages over the default operator class jsonb_ops. A jsonb_path_ops index is usually much smaller than a jsonb_ops index over the same data, and the specificity of searches is better, particularly when queries contain keys that appear frequently in the data. Therefore search operations typically perform better than with the default operator class.

The technical difference between a jsonb_ops and a jsonb_path_ops GIN index is that the former creates independent index items for each key and value in the data, while the latter creates index items only for each value in the data. 1 Basically, each jsonb_path_ops index item is a hash of the value and the key(s) leading to it; for example to index {"foo": {"bar": "baz"}}, a single index item would

1 For this purpose, the term “value” includes array elements, though JSON terminology sometimes considers array elements distinct from values within objects.
be created incorporating all three of foo, bar, and baz into the hash value. Thus a containment query looking for this structure would result in an extremely specific index search; but there is no way at all to find out whether foo appears as a key. On the other hand, a jsonb_ops index would create three index items representing foo, bar, and baz separately; then to do the containment query, it would look for rows containing all three of these items. While GIN indexes can perform such an AND search fairly efficiently, it will still be less specific and slower than the equivalent jsonb_path_ops search, especially if there are a very large number of rows containing any single one of the three index items.

A disadvantage of the jsonb_path_ops approach is that it produces no index entries for JSON structures not containing any values, such as {"a": {}}. If a search for documents containing such a structure is requested, it will require a full-index scan, which is quite slow. jsonb_path_ops is therefore ill-suited for applications that often perform such searches.

jsonb also supports btree and hash indexes. These are usually useful only if it’s important to check equality of complete JSON documents. The btree ordering for jsonb datums is seldom of great interest, but for completeness it is:

Object > Array > Boolean > Number > String > Null

Object with n pairs > object with n - 1 pairs

Array with n elements > array with n - 1 elements

Objects with equal numbers of pairs are compared in the order:

key-1, value-1, key-2 ...

Note that object keys are compared in their storage order; in particular, since shorter keys are stored before longer keys, this can lead to results that might be unintuitive, such as:

{ "aa": 1, "c": 1} > {"b": 1, "d": 1}

Similarly, arrays with equal numbers of elements are compared in the order:

element-1, element-2 ...

Primitive JSON values are compared using the same comparison rules as for the underlying Postgres Pro data type. Strings are compared using the default database collation.

8.14.5. jsonb Subscripting

The jsonb data type supports array-style subscripting expressions to extract and modify elements. Nested values can be indicated by chaining subscripting expressions, following the same rules as the path argument in the jsonb_set function. If a jsonb value is an array, numeric subscripts start at zero, and negative integers count backwards from the last element of the array. Slice expressions are not supported. The result of a subscripting expression is always of the jsonb data type.

UPDATE statements may use subscripting in the SET clause to modify jsonb values. Subscript paths must be traversable for all affected values insofar as they exist. For instance, the path val['a'][['b'][['c']] can be traversed all the way to c if every val, val['a'], and val['a'][['b'] is an object. If any val['a'] or val['a'][['b']] is not defined, it will be created as an empty object and filled as necessary. However, if any val itself or one of the intermediary values is defined as a non-object such as a string, number, or jsonb null, traversal cannot proceed so an error is raised and the transaction aborted.

An example of subscripting syntax:

-- Extract object value by key
SELECT ('{"a": 1}':::jsonb)['a'];

-- Extract nested object value by key path
SELECT ('{"a": {"b":{"c": 1}}}'::jsonb)['a'][['b'][['c']];
Data Types

-- Extract array element by index
SELECT ('[1, "2", null]::jsonb')[1];

-- Update object value by key. Note the quotes around '1': the assigned
-- value must be of the jsonb type as well
UPDATE table_name SET jsonb_field['key'] = '1';

-- This will raise an error if any record's jsonb_field['a']['b'] is something
-- other than an object. For example, the value ({"a": 1}) has a numeric value
-- of the key 'a'.
UPDATE table_name SET jsonb_field['a']['b']['c'] = '1';

-- Filter records using a WHERE clause with subscripting. Since the result of
-- subscripting is jsonb, the value we compare it against must also be jsonb.
-- The double quotes make "value" also a valid jsonb string.
SELECT * FROM table_name WHERE jsonb_field['key'] = '"value"';

jsonb assignment via subscripting handles a few edge cases differently from jsonb_set. When a source
jsonb value is NULL, assignment via subscripting will proceed as if it was an empty JSON value of the
type (object or array) implied by the subscript key:
-- Where jsonb_field was NULL, it is now {"a": 1}
UPDATE table_name SET jsonb_field['a'] = '1';

-- Where jsonb_field was NULL, it is now [1]
UPDATE table_name SET jsonb_field[0] = '1';

If an index is specified for an array containing too few elements, NULL elements will be appended until
the index is reachable and the value can be set.

-- Where jsonb_field was [], it is now [null, null, 2];
-- where jsonb_field was [0], it is now [0, null, 2]
UPDATE table_name SET jsonb_field[2] = '2';

A jsonb value will accept assignments to nonexistent subscript paths as long as the last existing element
to be traversed is an object or array, as implied by the corresponding subscript (the element indicated by
the last subscript in the path is not traversed and may be anything). Nested array and object structures
will be created, and in the former case null-padded, as specified by the subscript path until the assigned
value can be placed.

-- Where jsonb_field was {}, it is now {'a': [{'b': 1}]}
UPDATE table_name SET jsonb_field['a'][0]['b'] = '1';

-- Where jsonb_field was [], it is now [null, {'a': 1}]
UPDATE table_name SET jsonb_field[1]['a'] = '1';

8.14.6. Transforms

Additional extensions are available that implement transforms for the jsonb type for different procedural
languages.

The extensions for PL/Perl are called jsonb_plperl and jsonb_plperlu. If you use them, jsonb values
are mapped to Perl arrays, hashes, and scalars, as appropriate.

The extensions for PL/Python are called jsonb_plpythonu, jsonb_plpython2u, and jsonb_plpython3u
(see Section 44.1 for the PL/Python naming convention). If you use them, jsonb values are mapped to
Python dictionaries, lists, and scalars, as appropriate.

Of these extensions, jsonb_plperl is considered “trusted”, that is, it can be installed by non-superusers
who have CREATE privilege on the current database. The rest require superuser privilege to install.

8.14.7. jsonpath Type
The `jsonpath` type implements support for the SQL/JSON path language in Postgres Pro to efficiently query JSON data. It provides a binary representation of the parsed SQL/JSON path expression that specifies the items to be retrieved by the path engine from the JSON data for further processing with the SQL/JSON query functions.

The semantics of SQL/JSON path predicates and operators generally follow SQL. At the same time, to provide a natural way of working with JSON data, SQL/JSON path syntax uses some JavaScript conventions:

- Dot (.) is used for member access.
- Square brackets ([]) are used for array access.
- SQL/JSON arrays are 0-relative, unlike regular SQL arrays that start from 1.

An SQL/JSON path expression is typically written in an SQL query as an SQL character string literal, so it must be enclosed in single quotes, and any single quotes desired within the value must be doubled (see Section 4.1.2.1). Some forms of path expressions require string literals within them. These embedded string literals follow JavaScript/ECMAScript conventions: they must be surrounded by double quotes, and backslash escapes may be used within them to represent otherwise-hard-to-type characters. In particular, the way to write a double quote within an embedded string literal is `"`, and to write a backslash itself, you must write `\\`. Other special backslash sequences include those recognized in JSON strings: `\b`, `\f`, `\n`, `\r`, `\t`, `\v` for various ASCII control characters, and `\uNNNN` for a Unicode character identified by its 4-hex-digit code point. The backslash syntax also includes two cases not allowed by JSON: `\xNN` for a character code written with only two hex digits, and `\u{N...}` for a character code written with 1 to 6 hex digits.

A path expression consists of a sequence of path elements, which can be any of the following:

- Path literals of JSON primitive types: Unicode text, numeric, true, false, or null.
- Path variables listed in Table 8.24.
- Accessor operators listed in Table 8.25.
- `jsonpath` operators and methods listed in Section 9.16.2.2.
- Parentheses, which can be used to provide filter expressions or define the order of path evaluation.

For details on using `jsonpath` expressions with SQL/JSON query functions, see Section 9.16.2.

Table 8.24. `jsonpath` Variables

<table>
<thead>
<tr>
<th>Variable</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>$</td>
<td>A variable representing the JSON value being queried (the context item).</td>
</tr>
<tr>
<td>$varname</td>
<td>A named variable. Its value can be set by the parameter <code>vars</code> of several JSON processing functions; see Table 9.47 for details.</td>
</tr>
<tr>
<td>@</td>
<td>A variable representing the result of path evaluation in filter expressions.</td>
</tr>
</tbody>
</table>

Table 8.25. `jsonpath` Accessors

<table>
<thead>
<tr>
<th>Accessor Operator</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>.key</td>
<td>Member accessor that returns an object member with the specified key. If the key name matches some named variable starting with $ or does not meet the JavaScript rules for an identifier, it must be enclosed in double quotes to make it a string literal.</td>
</tr>
<tr>
<td>.&quot;$varname&quot;</td>
<td>Wildcard member accessor that returns the values of all members located at the top level of the current object.</td>
</tr>
</tbody>
</table>
| .**               | Recursive wildcard member accessor that processes all levels of the JSON hierarchy of the current object and returns all the

<th>Accessor Operator</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>**{level}</code></td>
<td>Member values, regardless of their nesting level. This is a Postgres Pro extension of the SQL/JSON standard.</td>
</tr>
<tr>
<td><code>**{start_level to end_level}</code></td>
<td>Like <code>**</code>, but selects only the specified levels of the JSON hierarchy. Nesting levels are specified as integers. Level zero corresponds to the current object. To access the lowest nesting level, you can use the <code>last</code> keyword. This is a Postgres Pro extension of the SQL/JSON standard.</td>
</tr>
<tr>
<td><code>[subscript, ...]</code></td>
<td>Array element accessor. <code>subscript</code> can be given in two forms: <code>index</code> or <code>start_index to end_index</code>. The first form returns a single array element by its index. The second form returns an array slice by the range of indexes, including the elements that correspond to the provided <code>start_index</code> and <code>end_index</code>. The specified <code>index</code> can be an integer, as well as an expression returning a single numeric value, which is automatically cast to integer. Index zero corresponds to the first array element. You can also use the <code>last</code> keyword to denote the last array element, which is useful for handling arrays of unknown length.</td>
</tr>
<tr>
<td><code>[*]</code></td>
<td>Wildcard array element accessor that returns all array elements.</td>
</tr>
</tbody>
</table>

### 8.15. Arrays

Postgres Pro allows columns of a table to be defined as variable-length multidimensional arrays. Arrays of any built-in or user-defined base type, enum type, composite type, range type, or domain can be created.

#### 8.15.1. Declaration of Array Types

To illustrate the use of array types, we create this table:

```sql
CREATE TABLE sal_emp (  
    name            text,  
    pay_by_quarter  integer[],  
    schedule        text[][]  
);  
```

As shown, an array data type is named by appending square brackets ([]) to the data type name of the array elements. The above command will create a table named `sal_emp` with a column of type `text` (name), a one-dimensional array of type `integer` (pay_by_quarter), which represents the employee's salary by quarter, and a two-dimensional array of `text` (schedule), which represents the employee's weekly schedule.

The syntax for `CREATE TABLE` allows the exact size of arrays to be specified, for example:

```sql
CREATE TABLE tictactoe (  
    squares   integer[3][3]  
);  
```

However, the current implementation ignores any supplied array size limits, i.e., the behavior is the same as for arrays of unspecified length.

The current implementation does not enforce the declared number of dimensions either. Arrays of a particular element type are all considered to be of the same type, regardless of size or number of dimensions. So, declaring the array size or number of dimensions in `CREATE TABLE` is simply documentation; it does not affect run-time behavior.

An alternative syntax, which conforms to the SQL standard by using the keyword `ARRAY`, can be used for one-dimensional arrays. `pay_by_quarter` could have been defined as:

```sql
pay_by_quarter  integer ARRAY[4],  
```
Or, if no array size is to be specified:

```sql
pay_by_quarter integer ARRAY,
```

As before, however, Postgres Pro does not enforce the size restriction in any case.

### 8.15.2. Array Value Input

To write an array value as a literal constant, enclose the element values within curly braces and separate them by commas. (If you know C, this is not unlike the C syntax for initializing structures.) You can put double quotes around any element value, and must do so if it contains commas or curly braces. (More details appear below.) Thus, the general format of an array constant is the following:

```sql
'{ val1 delim val2 delim ... }'
```

where `delim` is the delimiter character for the type, as recorded in its `pg_type` entry. Among the standard data types provided in the Postgres Pro distribution, all use a comma (,), except for type `box` which uses a semicolon (;). Each `val` is either a constant of the array element type, or a subarray. An example of an array constant is:

```sql
'{1,2,3},{4,5,6},{7,8,9}'
```

This constant is a two-dimensional, 3-by-3 array consisting of three subarrays of integers.

To set an element of an array constant to NULL, write `NULL` for the element value. (Any upper- or lowercase variant of `NULL` will do.) If you want an actual string value "NULL", you must put double quotes around it.

(These kinds of array constants are actually only a special case of the generic type constants discussed in Section 4.1.2.7. The constant is initially treated as a string and passed to the array input conversion routine. An explicit type specification might be necessary.)

Now we can show some `INSERT` statements:

```sql
INSERT INTO sal_emp
VALUES ('Bill',
'{{"meeting", "lunch"}, {"training", "presentation"}}');
```

```sql
INSERT INTO sal_emp
VALUES ('Carol',
'{{"breakfast", "consulting"}, {"meeting", "lunch"}}');
```

The result of the previous two inserts looks like this:

```sql
SELECT * FROM sal_emp;
```

<table>
<thead>
<tr>
<th>name</th>
<th>pay_by_quarter</th>
<th>schedule</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bill</td>
<td>{10000, 10000, 10000, 10000}</td>
<td>{{&quot;meeting&quot;, &quot;lunch&quot;}, {&quot;training&quot;, &quot;presentation&quot;}}</td>
</tr>
<tr>
<td>Carol</td>
<td>{20000, 25000, 25000, 25000}</td>
<td>{{&quot;breakfast&quot;, &quot;consulting&quot;}, {&quot;meeting&quot;, &quot;lunch&quot;}}</td>
</tr>
</tbody>
</table>

(2 rows)

Multidimensional arrays must have matching extents for each dimension. A mismatch causes an error, for example:

```sql
INSERT INTO sal_emp
VALUES ('Bill',
'{{"meeting", "lunch"}, {"meeting"}}');
```

**ERROR:** multidimensional arrays must have array expressions with matching dimensions

The `ARRAY` constructor syntax can also be used:

```sql
INSERT INTO sal_emp
```
VALUES ('Bill',
ARRAY[10000, 10000, 10000, 10000],
ARRAY[['meeting', 'lunch'], ['training', 'presentation']]);

INSERT INTO sal_emp
VALUES ('Carol',
ARRAY[20000, 25000, 25000, 25000],
ARRAY[['breakfast', 'consulting'], ['meeting', 'lunch']]);

Notice that the array elements are ordinary SQL constants or expressions; for instance, string literals are single quoted, instead of double quoted as they would be in an array literal. The ARRAY constructor syntax is discussed in more detail in Section 4.2.12.

8.15.3. Accessing Arrays

Now, we can run some queries on the table. First, we show how to access a single element of an array. This query retrieves the names of the employees whose pay changed in the second quarter:

```sql
SELECT name FROM sal_emp WHERE pay_by_quarter[1] <> pay_by_quarter[2];
```

<table>
<thead>
<tr>
<th>name</th>
</tr>
</thead>
<tbody>
<tr>
<td>Carol</td>
</tr>
</tbody>
</table>

(1 row)

The array subscript numbers are written within square brackets. By default Postgres Pro uses a one-based numbering convention for arrays, that is, an array of \( n \) elements starts with array[1] and ends with array[\( n \)].

This query retrieves the third quarter pay of all employees:

```sql
SELECT pay_by_quarter[3] FROM sal_emp;
```

<table>
<thead>
<tr>
<th>pay_by_quarter</th>
</tr>
</thead>
<tbody>
<tr>
<td>10000</td>
</tr>
<tr>
<td>25000</td>
</tr>
</tbody>
</table>

(2 rows)

We can also access arbitrary rectangular slices of an array, or subarrays. An array slice is denoted by writing lower-bound:upper-bound for one or more array dimensions. For example, this query retrieves the first item on Bill's schedule for the first two days of the week:

```sql
SELECT schedule[1:2][1:1] FROM sal_emp WHERE name = 'Bill';
```

<table>
<thead>
<tr>
<th>schedule</th>
</tr>
</thead>
<tbody>
<tr>
<td>{{meeting},{training}}</td>
</tr>
</tbody>
</table>

(1 row)

If any dimension is written as a slice, i.e., contains a colon, then all dimensions are treated as slices. Any dimension that has only a single number (no colon) is treated as being from 1 to the number specified. For example, [2] is treated as [1:2], as in this example:

```sql
SELECT schedule[1:2][2] FROM sal_emp WHERE name = 'Bill';
```

<table>
<thead>
<tr>
<th>schedule</th>
</tr>
</thead>
<tbody>
<tr>
<td>{{meeting,lunch},{training,presentation}}</td>
</tr>
</tbody>
</table>

(1 row)

To avoid confusion with the non-slice case, it's best to use slice syntax for all dimensions, e.g., [1:2] [1:1], not [2][1:1].
It is possible to omit the lower-bound and/or upper-bound of a slice specifier; the missing bound is replaced by the lower or upper limit of the array's subscripts. For example:

```sql
SELECT schedule[:2][2:] FROM sal_emp WHERE name = 'Bill';
```

```
schedule
--------
{{lunch},{presentation}}
(1 row)
```

```sql
SELECT schedule[:][1:1] FROM sal_emp WHERE name = 'Bill';
```

```
schedule
--------
{{meeting},{training}}
(1 row)
```

An array subscript expression will return null if either the array itself or any of the subscript expressions are null. Also, null is returned if a subscript is outside the array bounds (this case does not raise an error). For example, if `schedule` currently has the dimensions `[1:3][1:2]` then referencing `schedule[3][3]` yields NULL. Similarly, an array reference with the wrong number of subscripts yields a null rather than an error.

An array slice expression likewise yields null if the array itself or any of the subscript expressions are null. However, in other cases such as selecting an array slice that is completely outside the current array bounds, a slice expression yields an empty (zero-dimensional) array instead of null. (This does not match non-slice behavior and is done for historical reasons.) If the requested slice partially overlaps the array bounds, then it is silently reduced to just the overlapping region instead of returning null.

The current dimensions of any array value can be retrieved with the `array_dims` function:

```sql
SELECT array_dims(schedule) FROM sal_emp WHERE name = 'Carol';
```

```
array_dims
---------
[1:2][1:2]
(1 row)
```

`array_dims` produces a text result, which is convenient for people to read but perhaps inconvenient for programs. Dimensions can also be retrieved with `array_upper` and `array_lower`, which return the upper and lower bound of a specified array dimension, respectively:

```sql
SELECT array_upper(schedule, 1) FROM sal_emp WHERE name = 'Carol';
```

```
array_upper
----------
2
(1 row)
```

`array_length` will return the length of a specified array dimension:

```sql
SELECT array_length(schedule, 1) FROM sal_emp WHERE name = 'Carol';
```

```
array_length
-----------
2
(1 row)
```

`cardinality` returns the total number of elements in an array across all dimensions. It is effectively the number of rows a call to `unnest` would yield:

```sql
SELECT cardinality(schedule) FROM sal_emp WHERE name = 'Carol';
```
### 8.15.4. Modifying Arrays

An array value can be replaced completely:

```sql
UPDATE sal_emp SET pay_by_quarter = '{25000,25000,27000,27000}'
WHERE name = 'Carol';
```

or using the `ARRAY` expression syntax:

```sql
UPDATE sal_emp SET pay_by_quarter = ARRAY[25000,25000,27000,27000]
WHERE name = 'Carol';
```

An array can also be updated at a single element:

```sql
WHERE name = 'Bill';
```

or updated in a slice:

```sql
UPDATE sal_emp SET pay_by_quarter[1:2] = '{27000,27000}'
WHERE name = 'Carol';
```

The slice syntaxes with omitted `lower-bound` and/or `upper-bound` can be used too, but only when updating an array value that is not NULL or zero-dimensional (otherwise, there is no existing subscript limit to substitute).

A stored array value can be enlarged by assigning to elements not already present. Any positions between those previously present and the newly assigned elements will be filled with nulls. For example, if array `myarray` currently has 4 elements, it will have six elements after an update that assigns to `myarray[6]; myarray[5]` will contain null. Currently, enlargement in this fashion is only allowed for one-dimensional arrays, not multidimensional arrays.

Subscripted assignment allows creation of arrays that do not use one-based subscripts. For example one might assign to `myarray[-2:7]` to create an array with subscript values from -2 to 7.

New array values can also be constructed using the concatenation operator, `||`:

```sql
SELECT ARRAY[1,2] || ARRAY[3,4];
?column?
-----------
{1,2,3,4}
(1 row)
```

```sql
SELECT ARRAY[5,6] || ARRAY[[1,2],[3,4]];  
?column?
-------------
{{5,6},{1,2},{3,4}}
(1 row)
```

The concatenation operator allows a single element to be pushed onto the beginning or end of a one-dimensional array. It also accepts two `N`-dimensional arrays, or an `N`-dimensional and an `N+1`-dimensional array.

When a single element is pushed onto either the beginning or end of a one-dimensional array, the result is an array with the same lower bound subscript as the array operand. For example:

```sql
SELECT array_dims(1 || '{0:1}={2,3}':int[]);
array_dims
```

161
SELECT array_dims(ARRAY[1,2] || 3);
array_dims
[1:3]
(1 row)

When two arrays with an equal number of dimensions are concatenated, the result retains the lower
bound subscript of the left-hand operand's outer dimension. The result is an array comprising every
element of the left-hand operand followed by every element of the right-hand operand. For example:

SELECT array_dims(ARRAY[1,2] || ARRAY[3,4,5]);
array_dims
[1:5]
(1 row)

SELECT array_dims(ARRAY([[1,2],[3,4]]) || ARRAY([[5,6],[7,8],[9,0]]));
array_dims
[1:5][1:2]
(1 row)

When an N-dimensional array is pushed onto the beginning or end of an N+1-dimensional array, the result
is analogous to the element-array case above. Each N-dimensional sub-array is essentially an element of
the N+1-dimensional array's outer dimension. For example:

SELECT array_dims(ARRAY[1,2] || ARRAY[[3,4],[5,6]]);
array_dims
[1:3][1:2]
(1 row)

An array can also be constructed by using the functions array_prepend, array_append, or array_cat. The first two only support one-dimensional arrays, but array_cat supports multidimensional arrays. Some examples:

SELECT array_prepend(1, ARRAY[2,3]);
array_prepend
{1,2,3}
(1 row)

SELECT array_append(ARRAY[1,2], 3);
array_append
{1,2,3}
(1 row)

SELECT array_cat(ARRAY[1,2], ARRAY[3,4]);
array_cat
{1,2,3,4}
(1 row)

SELECT array_cat(ARRAY([[1,2],[3,4]]), ARRAY[5,6]);
array_cat
{1,2,3,4,5,6}
(1 row)
In simple cases, the concatenation operator discussed above is preferred over direct use of these functions. However, because the concatenation operator is overloaded to serve all three cases, there are situations where use of one of the functions is helpful to avoid ambiguity. For example consider:

SELECT ARRAY[1, 2] || '{3, 4}';  -- the untyped literal is taken as an array

-----------

{1,2,3,4}

SELECT ARRAY[1, 2] || '7';                 -- so is this one
ERROR: malformed array literal: "7"

SELECT ARRAY[1, 2] || NULL;                -- so is an undecorated NULL

-----------

{1,2}

SELECT array_append(ARRAY[1, 2], NULL);    -- this might have been meant

array_append

-----------

{1,2,NULL}

In the examples above, the parser sees an integer array on one side of the concatenation operator, and a constant of undetermined type on the other. The heuristic it uses to resolve the constant’s type is to assume it’s of the same type as the operator’s other input — in this case, integer array. So the concatenation operator is presumed to represent array_cat, not array_append. When that’s the wrong choice, it could be fixed by casting the constant to the array’s element type; but explicit use of array_append might be a preferable solution.

### 8.15.5. Searching in Arrays

To search for a value in an array, each value must be checked. This can be done manually, if you know the size of the array. For example:

```
SELECT * FROM sal_emp WHERE pay_by_quarter[1] = 10000 OR
  pay_by_quarter[2] = 10000 OR
  pay_by_quarter[3] = 10000 OR
  pay_by_quarter[4] = 10000;
```

However, this quickly becomes tedious for large arrays, and is not helpful if the size of the array is unknown. An alternative method is described in Section 9.24. The above query could be replaced by:

```
SELECT * FROM sal_emp WHERE 10000 = ANY (pay_by_quarter);
```

In addition, you can find rows where the array has all values equal to 10000 with:

```
SELECT * FROM sal_emp WHERE 10000 = ALL (pay_by_quarter);
```

Alternatively, the `generate_subscripts` function can be used. For example:

```
SELECT * FROM
  (SELECT pay_by_quarter,
       generate_subscripts(pay_by_quarter, 1) AS s
```
FROM sal_emp) AS foo
WHERE pay_by_quarter[s] = 10000;

This function is described in Table 9.64.

You can also search an array using the `&&` operator, which checks whether the left operand overlaps with the right operand. For instance:

```sql
SELECT * FROM sal_emp WHERE pay_by_quarter && ARRAY[10000];
```

This and other array operators are further described in Section 9.19. It can be accelerated by an appropriate index, as described in Section 11.2.

You can also search for specific values in an array using the `array_position` and `array_positions` functions. The former returns the subscript of the first occurrence of a value in an array; the latter returns an array with the subscripts of all occurrences of the value in the array. For example:

```sql
SELECT array_position(ARRAY['sun','mon','tue','wed','thu','fri','sat'], 'mon');
```

<table>
<thead>
<tr>
<th>array_position</th>
</tr>
</thead>
<tbody>
<tr>
<td>2</td>
</tr>
<tr>
<td>(1 row)</td>
</tr>
</tbody>
</table>

```sql
SELECT array_positions(ARRAY[1, 4, 3, 1, 3, 4, 2, 1], 1);
```

<table>
<thead>
<tr>
<th>array_positions</th>
</tr>
</thead>
<tbody>
<tr>
<td>{1,4,8}</td>
</tr>
<tr>
<td>(1 row)</td>
</tr>
</tbody>
</table>

Tip

Arrays are not sets; searching for specific array elements can be a sign of database misdesign. Consider using a separate table with a row for each item that would be an array element. This will be easier to search, and is likely to scale better for a large number of elements.

8.15.6. Array Input and Output Syntax

The external text representation of an array value consists of items that are interpreted according to the I/O conversion rules for the array's element type, plus decoration that indicates the array structure. The decoration consists of curly braces (`{` and `}`) around the array value plus delimiter characters between adjacent items. The delimiter character is usually a comma (`,`) but can be something else: it is determined by the `typdelim` setting for the array's element type. Among the standard data types provided in the Postgres Pro distribution, all use a comma, except for type `box`, which uses a semicolon (`;`). In a multidimensional array, each dimension (row, plane, cube, etc.) gets its own level of curly braces, and delimiters must be written between adjacent curly-braced entities of the same level.

The array output routine will put double quotes around element values if they are empty strings, contain curly braces, delimiter characters, double quotes, backslashes, or white space, or match the word `NULL`. Double quotes and backslashes embedded in element values will be backslash-escaped. For numeric data types it is safe to assume that double quotes will never appear, but for textual data types one should be prepared to cope with either the presence or absence of quotes.

By default, the lower bound index value of an array's dimensions is set to one. To represent arrays with other lower bounds, the array subscript ranges can be specified explicitly before writing the array contents. This decoration consists of square brackets (`[]`) around each array dimension's lower and upper bounds, with a colon `:` delimiter character in between. The array dimension decoration is followed by an equal sign `=`. For example:

```sql
SELECT f1[1][-2][3] AS e1, f1[1][-1][5] AS e2
FROM (SELECT '{1:1}[-2:-1][3:5]={{1,2,3},{4,5,6}}'::int[] AS f1) AS ss;
```
The array output routine will include explicit dimensions in its result only when there are one or more lower bounds different from one.

The value written for an element is NULL (in any case variant), the element is taken to be NULL. The presence of any quotes or backslashes disables this and allows the literal string value “NULL” to be entered. Also, for backward compatibility with pre-8.2 versions of PostgreSQL, the array_nulls configuration parameter can be turned off to suppress recognition of NULL as a NULL.

As shown previously, when writing an array value you can use double quotes around any individual array element. You must do so if the element value would otherwise confuse the array-value parser. For example, elements containing curly braces, commas (or the data type's delimiter character), double quotes, backslashes, or leading or trailing whitespace must be double-quoted. Empty strings and strings matching the word NULL must be quoted, too. To put a double quote or backslash in a quoted array element value, precede it with a backslash. Alternatively, you can avoid quotes and use backslash-escaping to protect all data characters that would otherwise be taken as array syntax.

You can add whitespace before a left brace or after a right brace. You can also add whitespace before or after any individual item string. In all of these cases the whitespace will be ignored. However, whitespace within double-quoted elements, or surrounded on both sides by non-whitespace characters of an element, is not ignored.

**Tip**
The ARRAY constructor syntax (see Section 4.2.12) is often easier to work with than the array-literal syntax when writing array values in SQL commands. In ARRAY, individual element values are written the same way they would be written when not members of an array.

### 8.16. Composite Types

A composite type represents the structure of a row or record; it is essentially just a list of field names and their data types. Postgres Pro allows composite types to be used in many of the same ways that simple types can be used. For example, a column of a table can be declared to be of a composite type.

#### 8.16.1. Declaration of Composite Types

Here are two simple examples of defining composite types:

```
CREATE TYPE complex AS (  
  r  double precision,  
  i  double precision  
);
```

```
CREATE TYPE inventory_item AS (  
  name         text,  
  supplier_id  integer,  
  price        numeric  
);
```

The syntax is comparable to CREATE TABLE, except that only field names and types can be specified; no constraints (such as NOT NULL) can presently be included. Note that the AS keyword is essential; without it, the system will think a different kind of CREATE TYPE command is meant, and you will get odd syntax errors.
Having defined the types, we can use them to create tables:

```
CREATE TABLE on_hand (  
    item    inventory_item,
    count   integer
);
```

```
INSERT INTO on_hand VALUES (ROW('fuzzy dice', 42, 1.99), 1000);
```

or functions:

```
CREATE FUNCTION price_extension(inventory_item, integer) RETURNS numeric  
AS 'SELECT $1.price * $2' LANGUAGE SQL;
```

```
SELECT price_extension(item, 10) FROM on_hand;
```

Whenever you create a table, a composite type is also automatically created, with the same name as the table, to represent the table’s row type. For example, had we said:

```
CREATE TABLE inventory_item (  
    name            text,
    supplier_id     integer REFERENCES suppliers,
    price           numeric CHECK (price > 0)
);
```

then the same `inventory_item` composite type shown above would come into being as a byproduct, and could be used just as above. Note however an important restriction of the current implementation: since no constraints are associated with a composite type, the constraints shown in the table definition do not apply to values of the composite type outside the table. (To work around this, create a domain over the composite type, and apply the desired constraints as CHECK constraints of the domain.)

### 8.16.2. Constructing Composite Values

To write a composite value as a literal constant, enclose the field values within parentheses and separate them by commas. You can put double quotes around any field value, and must do so if it contains commas or parentheses. (More details appear below.) Thus, the general format of a composite constant is the following:

```
'(val1, val2, ... )'
```

An example is:

```
('fuzzy dice",42,1.99')
```

which would be a valid value of the `inventory_item` type defined above. To make a field be NULL, write no characters at all in its position in the list. For example, this constant specifies a NULL third field:

```
'("fuzzy dice",42,)
```

If you want an empty string rather than NULL, write double quotes:

```
'("",42,)
```

Here the first field is a non-NULL empty string, the third is NULL.

(These constants are actually only a special case of the generic type constants discussed in Section 4.1.2.7. The constant is initially treated as a string and passed to the composite-type input conversion routine. An explicit type specification might be necessary to tell which type to convert the constant to.)

The `ROW` expression syntax can also be used to construct composite values. In most cases this is considerably simpler to use than the string-literal syntax since you don't have to worry about multiple layers of quoting. We already used this method above:

```
ROW('fuzzy dice', 42, 1.99)
ROW('', 42, NULL)
```
The ROW keyword is actually optional as long as you have more than one field in the expression, so these can be simplified to:

('fuzzy dice', 42, 1.99)
('', 42, NULL)

The ROW expression syntax is discussed in more detail in Section 4.2.13.

8.16.3. Accessing Composite Types

To access a field of a composite column, one writes a dot and the field name, much like selecting a field from a table name. In fact, it's so much like selecting from a table name that you often have to use parentheses to keep from confusing the parser. For example, you might try to select some subfields from our on_hand example table with something like:

SELECT item.name FROM on_hand WHERE item.price > 9.99;

This will not work since the name item is taken to be a table name, not a column name of on_hand, per SQL syntax rules. You must write it like this:

SELECT (item).name FROM on_hand WHERE (item).price > 9.99;

or if you need to use the table name as well (for instance in a multitable query), like this:

SELECT (on_hand.item).name FROM on_hand WHERE (on_hand.item).price > 9.99;

Now the parenthesized object is correctly interpreted as a reference to the item column, and then the subfield can be selected from it.

Similar syntactic issues apply whenever you select a field from a composite value. For instance, to select just one field from the result of a function that returns a composite value, you’d need to write something like:

SELECT (my_func(...)).field FROM ...

Without the extra parentheses, this will generate a syntax error.

The special field name * means “all fields”, as further explained in Section 8.16.5.

8.16.4. Modifying Composite Types

Here are some examples of the proper syntax for inserting and updating composite columns. First, inserting or updating a whole column:

INSERT INTO mytab (complex_col) VALUES((1.1,2.2));

UPDATE mytab SET complex_col = ROW(1.1,2.2) WHERE ...;

The first example omits ROW, the second uses it; we could have done it either way.

We can update an individual subfield of a composite column:

UPDATE mytab SET complex_col.r = (complex_col).r + 1 WHERE ...;

Notice here that we don't need to (and indeed cannot) put parentheses around the column name appearing just after SET, but we do need parentheses when referencing the same column in the expression to the right of the equal sign.

And we can specify subfields as targets for INSERT, too:

INSERT INTO mytab (complex_col.r, complex_col.i) VALUES(1.1, 2.2);

Had we not supplied values for all the subfields of the column, the remaining subfields would have been filled with null values.

8.16.5. Using Composite Types in Queries

There are various special syntax rules and behaviors associated with composite types in queries. These rules provide useful shortcuts, but can be confusing if you don't know the logic behind them.
In Postgres Pro, a reference to a table name (or alias) in a query is effectively a reference to the composite value of the table’s current row. For example, if we had a table `inventory_item` as shown above, we could write:

```sql
SELECT c FROM inventory_item c;
```

This query produces a single composite-valued column, so we might get output like:

```
c
------------------------
("fuzzy dice",42,1.99)
(1 row)
```

Note however that simple names are matched to column names before table names, so this example works only because there is no column named `c` in the query’s tables.

The ordinary qualified-column-name syntax `table_name.column_name` can be understood as applying field selection to the composite value of the table’s current row. (For efficiency reasons, it’s not actually implemented that way.)

When we write

```sql
SELECT c.* FROM inventory_item c;
```

then, according to the SQL standard, we should get the contents of the table expanded into separate columns:

```
<table>
<thead>
<tr>
<th>name</th>
<th>supplier_id</th>
<th>price</th>
</tr>
</thead>
<tbody>
<tr>
<td>fuzzy dice</td>
<td>42</td>
<td>1.99</td>
</tr>
</tbody>
</table>
```

as if the query were

```sql
SELECT c.name, c.supplier_id, c.price FROM inventory_item c;
```

Postgres Pro will apply this expansion behavior to any composite-valued expression, although as shown above, you need to write parentheses around the value that `*` is applied to whenever it’s not a simple table name. For example, if `myfunc()` is a function returning a composite type with columns `a`, `b`, and `c`, then these two queries have the same result:

```sql
SELECT (myfunc(x)).* FROM some_table;
SELECT (myfunc(x)).a, (myfunc(x)).b, (myfunc(x)).c FROM some_table;
```

Postgres Pro handles column expansion by actually transforming the first form into the second. So, in this example, `myfunc()` would get invoked three times per row with either syntax. If it’s an expensive function you may wish to avoid that, which you can do with a query like:

```sql
SELECT m.* FROM some_table, LATERAL myfunc(x) AS m;
```

Placing the function in a `LATERAL` FROM item keeps it from being invoked more than once per row. `m.*` is still expanded into `m.a`, `m.b`, `m.c`, but now those variables are just references to the output of the `FROM` item. (The `LATERAL` keyword is optional here, but we show it to clarify that the function is getting `x` from `some_table`.)

The `composite_value.*` syntax results in column expansion of this kind when it appears at the top level of a `SELECT output list`, a `RETURNING list` in `INSERT/UPDATE/DELETE`, a `VALUES clause`, or a `row constructor`. In all other contexts (including when nested inside one of those constructs), attaching `.*` to a composite value does not change the value, since it means “all columns” and so the same composite value is produced again. For example, if `somefunc()` accepts a composite-valued argument, these queries are the same:

```sql
SELECT somefunc(c.*) FROM inventory_item c;
```
SELECT somefunc(c) FROM inventory_item c;

In both cases, the current row of inventory_item is passed to the function as a single composite-valued argument. Even though .* does nothing in such cases, using it is good style, since it makes clear that a composite value is intended. In particular, the parser will consider c in c.* to refer to a table name or alias, not to a column name, so that there is no ambiguity; whereas without .*, it is not clear whether c means a table name or a column name, and in fact the column-name interpretation will be preferred if there is a column named c.

Another example demonstrating these concepts is that all these queries mean the same thing:

```
SELECT * FROM inventory_item c ORDER BY c;
SELECT * FROM inventory_item c ORDER BY c.);
SELECT * FROM inventory_item c ORDER BY ROW(c.*);
```

All of these ORDER BY clauses specify the row's composite value, resulting in sorting the rows according to the rules described in Section 9.24.6. However, if inventory_item contained a column named c, the first case would be different from the others, as it would mean to sort by that column only. Given the column names previously shown, these queries are also equivalent to those above:

```
SELECT * FROM inventory_item c ORDER BY ROW(c.name, c.supplier_id, c.price);
SELECT * FROM inventory_item c ORDER BY (c.name, c.supplier_id, c.price);
```

(The last case uses a row constructor with the key word ROW omitted.)

Another special syntactical behavior associated with composite values is that we can use functional notation for extracting a field of a composite value. The simple way to explain this is that the notations field(table) and table.field are interchangeable. For example, these queries are equivalent:

```
SELECT c.name FROM inventory_item c WHERE c.price > 1000;
SELECT name(c) FROM inventory_item c WHERE price(c) > 1000;
```

Moreover, if we have a function that accepts a single argument of a composite type, we can call it with either notation. These queries are all equivalent:

```
SELECT somefunc(c) FROM inventory_item c;
SELECT somefunc(c.*) FROM inventory_item c;
SELECT c.somefunc FROM inventory_item c;
```

This equivalence between functional notation and field notation makes it possible to use functions on composite types to implement “computed fields”. An application using the last query above wouldn’t need to be directly aware that somefunc isn't a real column of the table.

**Tip**

Because of this behavior, it's unwise to give a function that takes a single composite-type argument the same name as any of the fields of that composite type. If there is ambiguity, the field-name interpretation will be chosen if field-name syntax is used, while the function will be chosen if function-call syntax is used. However, PostgreSQL versions before 11 always chose the field-name interpretation, unless the syntax of the call required it to be a function call. One way to force the function interpretation in older versions is to schema-qualify the function name, that is, write `schema.func(compositevalue)`.

### 8.16.6. Composite Type Input and Output Syntax

The external text representation of a composite value consists of items that are interpreted according to the I/O conversion rules for the individual field types, plus decoration that indicates the composite structure. The decoration consists of parentheses ( and ) around the whole value, plus commas (,) between adjacent items. Whitespace outside the parentheses is ignored, but within the parentheses it is considered part of the field value, and might or might not be significant depending on the input conversion rules for the field data type. For example, in:
the whitespace will be ignored if the field type is integer, but not if it is text.

As shown previously, when writing a composite value you can write double quotes around any individual field value. You must do so if the field value would otherwise confuse the composite-value parser. In particular, fields containing parentheses, commas, double quotes, or backslashes must be double-quoted. To put a double quote or backslash in a quoted composite field value, precede it with a backslash. (Also, a pair of double quotes within a double-quoted field value is taken to represent a double quote character, analogously to the rules for single quotes in SQL literal strings.) Alternatively, you can avoid quoting and use backslash-escaping to protect all data characters that would otherwise be taken as composite syntax.

A completely empty field value (no characters at all between the commas or parentheses) represents a NULL. To write a value that is an empty string rather than NULL, write "".

The composite output routine will put double quotes around field values if they are empty strings or contain parentheses, commas, double quotes, backslashes, or white space. (Doing so for white space is not essential, but aids legibility.) Double quotes and backslashes embedded in field values will be doubled.

### Note

Remember that what you write in an SQL command will first be interpreted as a string literal, and then as a composite. This doubles the number of backslashes you need (assuming escape string syntax is used). For example, to insert a text field containing a double quote and a backslash in a composite value, you'd need to write:

```sql
INSERT ... VALUES ('""\""');
```

The string-literal processor removes one level of backslashes, so that what arrives at the composite-value parser looks like "\"\". In turn, the string fed to the text data type's input routine becomes \". (If we were working with a data type whose input routine also treated backslashes specially, bytea for example, we might need as many as eight backslashes in the command to get one backslash into the stored composite field.) Dollar quoting (see Section 4.1.2.4) can be used to avoid the need to double backslashes.

### Tip

The `ROW` constructor syntax is usually easier to work with than the composite-literal syntax when writing composite values in SQL commands. In `ROW`, individual field values are written the same way they would be written when not members of a composite.

### 8.17. Range Types

Range types are data types representing a range of values of some element type (called the range's *subtype*). For instance, ranges of `timestamp` might be used to represent the ranges of time that a meeting room is reserved. In this case the data type is `tsrange` (short for “timestamp range”), and `timestamp` is the subtype. The subtype must have a total order so that it is well-defined whether element values are within, before, or after a range of values.

Range types are useful because they represent many element values in a single range value, and because concepts such as overlapping ranges can be expressed clearly. The use of time and date ranges for scheduling purposes is the clearest example; but price ranges, measurement ranges from an instrument, and so forth can also be useful.

Every range type has a corresponding multirange type. A multirange is an ordered list of non-contiguous, non-empty, non-null ranges. Most range operators also work on multiranges, and they have a few functions of their own.
8.17.1. Built-in Range and Multirange Types

Postgres Pro comes with the following built-in range types:

- int4range — Range of integer, int4multirange — corresponding Multirange
- int8range — Range of bigint, int8multirange — corresponding Multirange
- numrange — Range of numeric, nummultirange — corresponding Multirange
- tsrange — Range of timestamp without time zone, tsmultirange — corresponding Multirange
- tstzrange — Range of timestamp with time zone, tstzmultirange — corresponding Multirange
- daterange — Range of date, datemultirange — corresponding Multirange

In addition, you can define your own range types; see CREATE TYPE for more information.

8.17.2. Examples

```
CREATE TABLE reservation (room int, during tsrange);
INSERT INTO reservation VALUES
  (1108, '[2010-01-01 14:30, 2010-01-01 15:30]');

-- Containment
SELECT int4range(10, 20) @> 3;

-- Overlaps
SELECT numrange(11.1, 22.2) && numrange(20.0, 30.0);

-- Extract the upper bound
SELECT upper(int8range(15, 25));

-- Compute the intersection
SELECT int4range(10, 20) * int4range(15, 25);

-- Is the range empty?
SELECT isempty(numrange(1, 5));
```

See Table 9.53 and Table 9.55 for complete lists of operators and functions on range types.

8.17.3. Inclusive and Exclusive Bounds

Every non-empty range has two bounds, the lower bound and the upper bound. All points between these values are included in the range. An inclusive bound means that the boundary point itself is included in the range as well, while an exclusive bound means that the boundary point is not included in the range.

In the text form of a range, an inclusive lower bound is represented by "[" while an exclusive lower bound is represented by "(". Likewise, an inclusive upper bound is represented by "]", while an exclusive upper bound is represented by ")". (See Section 8.17.5 for more details.)

The functions lower_inc and upper_inc test the inclusivity of the lower and upper bounds of a range value, respectively.

8.17.4. Infinite (Unbounded) Ranges

The lower bound of a range can be omitted, meaning that all values less than the upper bound are included in the range, e.g., (,.3]. Likewise, if the upper bound of the range is omitted, then all values greater than the lower bound are included in the range. If both lower and upper bounds are omitted, all values of the element type are considered to be in the range. Specifying a missing bound as inclusive is automatically converted to exclusive, e.g., [,] is converted to (.). You can think of these missing values as +/-infinity, but they are special range type values and are considered to be beyond any range element type's +/-infinity values.
Element types that have the notion of “infinity” can use them as explicit bound values. For example, with timestamp ranges, \([\text{today}, \infty)\) excludes the special timestamp value \(\infty\), while \([\text{today}, \infty]\) include it, as does \([\text{today},)\) and \([\text{today},]\).

The functions \(\text{lower\_inf}\) and \(\text{upper\_inf}\) test for infinite lower and upper bounds of a range, respectively.

### 8.17.5. Range Input/Output

The input for a range value must follow one of the following patterns:

- \((\text{lower-bound}, \text{upper-bound})\)
- \((\text{lower-bound}, \text{upper-bound}]\)
- \([\text{lower-bound}, \text{upper-bound})\)
- \([\text{lower-bound}, \text{upper-bound}]\)
- empty

The parentheses or brackets indicate whether the lower and upper bounds are exclusive or inclusive, as described previously. Notice that the final pattern is \(\text{empty}\), which represents an empty range (a range that contains no points).

The \(\text{lower-bound}\) may be either a string that is valid input for the subtype, or empty to indicate no lower bound. Likewise, \(\text{upper-bound}\) may be either a string that is valid input for the subtype, or empty to indicate no upper bound.

Each bound value can be quoted using " (double quote) characters. This is necessary if the bound value contains parentheses, brackets, commas, double quotes, or backslashes, since these characters would otherwise be taken as part of the range syntax. To put a double quote or backslash in a quoted bound value, precede it with a backslash. (Also, a pair of double quotes within a double-quoted bound value is taken to represent a double quote character, analogously to the rules for single quotes in SQL literal strings.) Alternatively, you can avoid quoting and use backslash-escaping to protect all data characters that would otherwise be taken as range syntax. Also, to write a bound value that is an empty string, write "\"", since writing nothing means an infinite bound.

Whitespace is allowed before and after the range value, but any whitespace between the parentheses or brackets is taken as part of the lower or upper bound value. (Depending on the element type, it might or might not be significant.)

#### Note

These rules are very similar to those for writing field values in composite-type literals. See Section 8.16.6 for additional commentary.

**Examples:**

-- includes 3, does not include 7, and does include all points in between
SELECT '\(3,7\)\)::\text{int4range};

-- does not include either 3 or 7, but includes all points in between
SELECT '\(3,7\)\)::\text{int4range};

-- includes only the single point 4
SELECT '\(4,4\)\)::\text{int4range};

-- includes no points (and will be normalized to 'empty')
SELECT '\(4,4\)\)::\text{int4range};

The input for a multirange is curly brackets (\{\ and \}) containing zero or more valid ranges, separated by commas. Whitespace is permitted around the brackets and commas. This is intended to be reminiscent of array syntax, although multiranges are much simpler: they have just one dimension and there is no need to quote their contents. (The bounds of their ranges may be quoted as above however.)
Examples:

SELECT '{}'::int4multirange;
SELECT '{[3,7)}'::int4multirange;
SELECT '{[3,7), [8,9)}'::int4multirange;

8.17.6. Constructing Ranges and Multiranges

Each range type has a constructor function with the same name as the range type. Using the constructor function is frequently more convenient than writing a range literal constant, since it avoids the need for extra quoting of the bound values. The constructor function accepts two or three arguments. The two-argument form constructs a range in standard form (lower bound inclusive, upper bound exclusive), while the three-argument form constructs a range with bounds of the form specified by the third argument. The third argument must be one of the strings "()", "()", "[]", or "[]". For example:

-- The full form is: lower bound, upper bound, and text argument indicating
-- inclusivity/exclusivity of bounds.
SELECT numrange(1.0, 14.0, '(');

-- If the third argument is omitted, '()' is assumed.
SELECT numrange(1.0, 14.0);

-- Although '()' is specified here, on display the value will be converted to
-- canonical form, since int8range is a discrete range type (see below).
SELECT int8range(1, 14, '(');

-- Using NULL for either bound causes the range to be unbounded on that side.
SELECT numrange(NULL, 2.2);

Each range type also has a multirange constructor with the same name as the multirange type. The constructor function takes zero or more arguments which are all ranges of the appropriate type. For example:

SELECT nummultirange();
SELECT nummultirange(numrange(1.0, 14.0));
SELECT nummultirange(numrange(1.0, 14.0), numrange(20.0, 25.0));

8.17.7. Discrete Range Types

A discrete range is one whose element type has a well-defined “step”, such as integer or date. In these types two elements can be said to be adjacent, when there are no valid values between them. This contrasts with continuous ranges, where it’s always (or almost always) possible to identify other element values between two given values. For example, a range over the numeric type is continuous, as is a range over timestamp. (Even though timestamp has limited precision, and so could theoretically be treated as discrete, it’s better to consider it continuous since the step size is normally not of interest.)

Another way to think about a discrete range type is that there is a clear idea of a “next” or “previous” value for each element value. Knowing that, it is possible to convert between inclusive and exclusive representations of a range's bounds, by choosing the next or previous element value instead of the one originally given. For example, in an integer range type \([4, 8]\) and \((3, 9)\) denote the same set of values; but this would not be so for a range over numeric.

A discrete range type should have a canonicalization function that is aware of the desired step size for the element type. The canonicalization function is charged with converting equivalent values of the range type to have identical representations, in particular consistently inclusive or exclusive bounds. If a canonicalization function is not specified, then ranges with different formatting will always be treated as unequal, even though they might represent the same set of values in reality.

The built-in range types int4range, int8range, and daterange all use a canonical form that includes the lower bound and excludes the upper bound; that is, {}. User-defined range types can use other conventions, however.
8.17.8. Defining New Range Types

Users can define their own range types. The most common reason to do this is to use ranges over subtypes not provided among the built-in range types. For example, to define a new range type of subtype float8:

```
CREATE TYPE floatrange AS RANGE (
  subtype = float8,
  subtype_diff = float8mi
);
```

```
SELECT '[1.234, 5.678]'::floatrange;
```

Because float8 has no meaningful “step”, we do not define a canonicalization function in this example.

When you define your own range you automatically get a corresponding multirange type.

Defining your own range type also allows you to specify a different subtype B-tree operator class or collation to use, so as to change the sort ordering that determines which values fall into a given range.

If the subtype is considered to have discrete rather than continuous values, the `CREATE TYPE` command should specify a canonical function. The canonicalization function takes an input range value and must return an equivalent range value that may have different bounds and formatting. The canonical output for two ranges that represent the same set of values, for example the integer ranges [1, 7) and [1, 8), must be identical. It doesn't matter which representation you choose to be the canonical one, so long as two equivalent values with different formattings are always mapped to the same value with the same formatting. In addition to adjusting the inclusive/exclusive bounds format, a canonicalization function might round off boundary values, in case the desired step size is larger than what the subtype is capable of storing. For instance, a range type over `timestamp` could be defined to have a step size of an hour, in which case the canonicalization function would need to round off bounds that weren’t a multiple of an hour, or perhaps throw an error instead.

In addition, any range type that is meant to be used with GiST or SP-GiST indexes should define a subtype difference, or `subtype_diff`, function. (The index will still work without `subtype_diff`, but it is likely to be considerably less efficient than if a difference function is provided.) The subtype difference function takes two input values of the subtype, and returns their difference (i.e., \( x - y \)) represented as a float8 value. In our example above, the function `float8mi` that underlies the regular float8 minus operator can be used; but for any other subtype, some type conversion would be necessary. Some creative thought about how to represent differences as numbers might be needed, too. To the greatest extent possible, the `subtype_diff` function should agree with the sort ordering implied by the selected operator class and collation; that is, its result should be positive whenever its first argument is greater than its second according to the sort ordering.

A less-oversimplified example of a `subtype_diff` function is:

```
CREATE FUNCTION time_subtype_diff(x time, y time) RETURNS float8 AS
' SELECT EXTRACT(EPOCH FROM (x - y))' LANGUAGE sql STRICT IMMUTABLE;
```

```
CREATE TYPE timerange AS RANGE (
  subtype = time,
  subtype_diff = time_subtype_diff
);
```

```
SELECT '[11:10, 23:00]':timerange;
```

See `CREATE TYPE` for more information about creating range types.

8.17.9. Indexing

GiST and SP-GiST indexes can be created for table columns of range types. GiST indexes can be also created for table columns of multirange types. For instance, to create a GiST index:
CREATE INDEX reservation_idx ON reservation USING GIST (during);

A GiST or SP-GiST index on ranges can accelerate queries involving these range operators: =, &&, <@, @>, <<, >>, |-, <, and >. A GiST index on multiranges can accelerate queries involving the same set of multirange operators. A GiST index on ranges and GiST index on multiranges can also accelerate queries involving these cross-type range to multirange and multirange to range operators correspondingly: &&, <@, @>, <<, >>, |-, <, and >. See Table 9.53 for more information.

In addition, B-tree and hash indexes can be created for table columns of range types. For these index types, basically the only useful range operation is equality. There is a B-tree sort ordering defined for range values, with corresponding < and > operators, but the ordering is rather arbitrary and not usually useful in the real world. Range types' B-tree and hash support is primarily meant to allow sorting and hashing internally in queries, rather than creation of actual indexes.

8.17.10. Constraints on Ranges

While UNIQUE is a natural constraint for scalar values, it is usually unsuitable for range types. Instead, an exclusion constraint is often more appropriate (see CREATE TABLE ... CONSTRAINT ... EXCLUDE). Exclusion constraints allow the specification of constraints such as "non-overlapping" on a range type. For example:

```
CREATE TABLE reservation (  
during tsrange,
   EXCLUDE USING GIST (during WITH &&)
);
```

That constraint will prevent any overlapping values from existing in the table at the same time:

```
INSERT INTO reservation VALUES  
('[2010-01-01 11:30, 2010-01-01 15:00)');
```

```
INSERT INTO reservation VALUES  
('[2010-01-01 14:45, 2010-01-01 15:45)');
ERROR: conflicting key value violates exclusion constraint "reservation_during_excl"
DETAIL: Key (during)=('[2010-01-01 14:45:00","2010-01-01 15:45:00"]) conflicts
with existing key (during)=('[2010-01-01 11:30:00","2010-01-01 15:00:00"]).
```

You can use the `btree_gist` extension to define exclusion constraints on plain scalar data types, which can then be combined with range exclusions for maximum flexibility. For example, after `btree_gist` is installed, the following constraint will reject overlapping ranges only if the meeting room numbers are equal:

```
CREATE EXTENSION btree_gist;
CREATE TABLE room_reservation (  
   room text,
   during tsrange,
   EXCLUDE USING GIST (room WITH =, during WITH &&)
);
```

```
INSERT INTO room_reservation VALUES  
('123A', '[2010-01-01 14:00, 2010-01-01 15:00)');
```

```
INSERT INTO room_reservation VALUES  
('123A', '[2010-01-01 14:30, 2010-01-01 15:30)');
ERROR: conflicting key value violates exclusion constraint "room_reservation_room_during_excl"
DETAIL: Key (room, during)=('123A, ["2010-01-01 14:30:00","2010-01-01 15:30:00"]) conflicts
with existing key (room, during)=('123A, ["2010-01-01 14:00:00","2010-01-01 15:00:00"]).
```
8.18. Domain Types

A domain is a user-defined data type that is based on another underlying type. Optionally, it can have constraints that restrict its valid values to a subset of what the underlying type would allow. Otherwise it behaves like the underlying type — for example, any operator or function that can be applied to the underlying type will work on the domain type. The underlying type can be any built-in or user-defined base type, enum type, array type, composite type, range type, or another domain.

For example, we could create a domain over integers that accepts only positive integers:

```
CREATE DOMAIN posint AS integer CHECK (VALUE > 0);
CREATE TABLE mytable (id posint);
INSERT INTO mytable VALUES(1);   -- works
INSERT INTO mytable VALUES(-1);  -- fails
```

When an operator or function of the underlying type is applied to a domain value, the domain is automatically down-cast to the underlying type. Thus, for example, the result of `mytable.id - 1` is considered to be of type `integer` not `posint`. We could write `(mytable.id - 1)::posint` to cast the result back to `posint`, causing the domain's constraints to be rechecked. In this case, that would result in an error if the expression had been applied to an `id` value of 1. Assigning a value of the underlying type to a field or variable of the domain type is allowed without writing an explicit cast, but the domain's constraints will be checked.

For additional information see CREATE DOMAIN.

8.19. Object Identifier Types

Object identifiers (OIDs) are used internally by Postgres Pro as primary keys for various system tables. Type `oid` represents an object identifier. There are also several alias types for `oid`, each named `regsomething`. Table 8.26 shows an overview.

The `oid` type is currently implemented as an unsigned four-byte integer. Therefore, it is not large enough to provide database-wide uniqueness in large databases, or even in large individual tables.

The `oid` type itself has few operations beyond comparison. It can be cast to `integer`, however, and then manipulated using the standard integer operators. (Beware of possible signed-versus-unsigned confusion if you do this.)

The OID alias types have no operations of their own except for specialized input and output routines. These routines are able to accept and display symbolic names for system objects, rather than the raw numeric value that type `oid` would use. The alias types allow simplified lookup of OID values for objects. For example, to examine the `pg_attribute` rows related to a table `mytable`, one could write:

```
SELECT * FROM pg_attribute WHERE attrelid = 'mytable'::regclass;
```

rather than:

```
SELECT * FROM pg_attribute
  WHERE attrelid = (SELECT oid FROM pg_class WHERE relname = 'mytable');
```

While that doesn't look all that bad by itself, it's still oversimplified. A far more complicated sub-select would be needed to select the right OID if there are multiple tables named `mytable` in different schemas. The `regclass` input converter handles the table lookup according to the schema path setting, and so it does the “right thing” automatically. Similarly, casting a table's OID to `regclass` is handy for symbolic display of a numeric OID.
### Table 8.26. Object Identifier Types

<table>
<thead>
<tr>
<th>Name</th>
<th>References</th>
<th>Description</th>
<th>Value Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>oid</td>
<td>any</td>
<td>numeric object identifier</td>
<td>564182</td>
</tr>
<tr>
<td>regclass</td>
<td>pg_class</td>
<td>relation name</td>
<td>pg_type</td>
</tr>
<tr>
<td>regcollation</td>
<td>pg_collation</td>
<td>collation name</td>
<td>&quot;POSIX&quot;</td>
</tr>
<tr>
<td>regconfig</td>
<td>pg_ts_config</td>
<td>text search configuration</td>
<td>english</td>
</tr>
<tr>
<td>regdictionary</td>
<td>pg_ts_dict</td>
<td>text search dictionary</td>
<td>simple</td>
</tr>
<tr>
<td>regnamespace</td>
<td>pg_namespace</td>
<td>namespace name</td>
<td>pg_catalog</td>
</tr>
<tr>
<td>regoperator</td>
<td>pg_operator</td>
<td>operator name</td>
<td>+</td>
</tr>
<tr>
<td>regprocedure</td>
<td>pg_proc</td>
<td>function name</td>
<td>sum</td>

<tr>
<td>regrole</td>
<td>pg_authid</td>
<td>role name</td>
<td>smithee</td>
</tr>
<tr>
<td>regtype</td>
<td>pg_type</td>
<td>data type name</td>
<td>integer</td>
</tr>
</tbody>
</table>

All of the OID alias types for objects that are grouped by namespace accept schema-qualified names, and will display schema-qualified names on output if the object would not be found in the current search path without being qualified. For example, `myschema.mytable` is acceptable input for `regclass` (if there is such a table). That value might be output as `myschema.mytable`, or just `mytable`, depending on the current search path. The `regproc` and `regoperator` alias types will only accept input names that are unique (not overloaded), so they are of limited use; for most uses `regprocedure` or `regoperator` are more appropriate. For `regoperator`, unary operators are identified by writing `NONE` for the unused operand.

The input functions for these types allow whitespace between tokens, and will fold upper-case letters to lower case, except within double quotes; this is done to make the syntax rules similar to the way object names are written in SQL. Conversely, the output functions will use double quotes if needed to make the output be a valid SQL identifier. For example, the OID of a function named `Foo` (with upper case F) taking two integer arguments could be entered as `'"Foo"(int4,int4)'::regprocedure`. The output would look like "Foo"(integer, integer). Both the function name and the argument type names could be schema-qualified, too.

Many built-in PostgreSQL functions accept the OID of a table, or another kind of database object, and for convenience are declared as taking `regclass` (or the appropriate OID alias type). This means you do not have to look up the object’s OID by hand, but can just enter its name as a string literal. For example, the `nextval(regclass)` function takes a sequence relation’s OID, so you could call it like this:

```
nextval('foo')  // operates on sequence foo
nextval('FOO')  // same as above
nextval("Foo") // operates on sequence Foo
nextval('myschema.foo') // operates on myschema.foo
nextval("myschema.foo") // same as above
nextval('foo')   // searches search path for foo
```

### Note

When you write the argument of such a function as an unadorned literal string, it becomes a constant of type `regclass` (or the appropriate type). Since this is really just an OID, it will track the originally identified object despite later renaming, schema reassignment, etc. This “early binding” behavior is usually desirable for object references in column defaults and views. But sometimes...
you might want “late binding” where the object reference is resolved at run time. To get late-binding behavior, force the constant to be stored as a text constant instead of regclass:

```sql
nextval('foo':text)  -- foo is looked up at runtime
```

The to_regclass() function and its siblings can also be used to perform run-time lookups. See Table 9.70.

Another practical example of use of regclass is to look up the OID of a table listed in the information_schema views, which don’t supply such OIDs directly. One might for example wish to call the pg_relation_size() function, which requires the table OID. Taking the above rules into account, the correct way to do that is

```sql
SELECT table_schema, table_name,
       pg_relation_size((quote_ident(table_schema) || '.' || quote_ident(table_name))::regclass)
FROM information_schema.tables
WHERE ...
```

The quote_ident() function will take care of double-quoting the identifiers where needed. The seemingly easier

```sql
SELECT pg_relation_size(table_name)
FROM information_schema.tables
WHERE ...
```

is not recommended, because it will fail for tables that are outside your search path or have names that require quoting.

An additional property of most of the OID alias types is the creation of dependencies. If a constant of one of these types appears in a stored expression (such as a column default expression or view), it creates a dependency on the referenced object. For example, if a column has a default expression `nextval('my_seq':regclass)`, Postgres Pro understands that the default expression depends on the sequence `my_seq`, so the system will not let the sequence be dropped without first removing the default expression. The alternative of `nextval('my_seq':text)` does not create a dependency. (`regrole` is an exception to this property. Constants of this type are not allowed in stored expressions.)

Another identifier type used by the system is xid, or transaction (abbreviated xact) identifier. This is the data type of the system columns xmin and xmax. Transaction identifiers are 32-bit quantities. In some contexts, a 64-bit variant xid8 is used. Unlike xid values, xid8 values increase strictly monotonically and cannot be reused in the lifetime of a database cluster.

A third identifier type used by the system is cid, or command identifier. This is the data type of the system columns cmin and cmax. Command identifiers are also 32-bit quantities.

A final identifier type used by the system is tid, or tuple identifier (row identifier). This is the data type of the system column ctid. A tuple ID is a pair (block number, tuple index within block) that identifies the physical location of the row within its table.

(The system columns are further explained in Section 5.5.)

### 8.20. pg_lsn Type

The pg_lsn data type can be used to store LSN (Log Sequence Number) data which is a pointer to a location in the WAL. This type is a representation of XLogRecPtr and an internal system type of Postgres Pro.

Internally, an LSN is a 64-bit integer, representing a byte position in the write-ahead log stream. It is printed as two hexadecimal numbers of up to 8 digits each, separated by a slash; for example, 16/B374D848. The pg_lsn type supports the standard comparison operators, like = and >. Two LSNs
can be subtracted using the \(-\) operator; the result is the number of bytes separating those write-ahead log locations. Also the number of bytes can be added into and subtracted from LSN using the \(+\)(pg_lsn,numeric) and \(-\)(pg_lsn,numeric) operators, respectively. Note that the calculated LSN should be in the range of pg_lsn type, i.e., between 0/0 and FFFFFFFF/FFFFFFFF.

8.21. Pseudo-Types

The Postgres Pro type system contains a number of special-purpose entries that are collectively called pseudo-types. A pseudo-type cannot be used as a column data type, but it can be used to declare a function's argument or result type. Each of the available pseudo-types is useful in situations where a function's behavior does not correspond to simply taking or returning a value of a specific SQL data type. Table 8.27 lists the existing pseudo-types.

Table 8.27. Pseudo-Types

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>any</td>
<td>Indicates that a function accepts any input data type.</td>
</tr>
<tr>
<td>anyelement</td>
<td>Indicates that a function accepts any data type (see Section 36.2.5).</td>
</tr>
<tr>
<td>anyarray</td>
<td>Indicates that a function accepts any array data type (see Section 36.2.5).</td>
</tr>
<tr>
<td>anynonarray</td>
<td>Indicates that a function accepts any non-array data type (see Section 36.2.5).</td>
</tr>
<tr>
<td>anyenum</td>
<td>Indicates that a function accepts any enum data type (see Section 36.2.5 and Section 8.7).</td>
</tr>
<tr>
<td>anyrange</td>
<td>Indicates that a function accepts any range data type (see Section 36.2.5 and Section 8.17).</td>
</tr>
<tr>
<td>anymultirange</td>
<td>Indicates that a function accepts any multirange data type (see Section 36.2.5 and Section 8.17).</td>
</tr>
<tr>
<td>anycompatible</td>
<td>Indicates that a function accepts any data type, with automatic promotion of multiple arguments to a common data type (see Section 36.2.5).</td>
</tr>
<tr>
<td>anycompatiblearray</td>
<td>Indicates that a function accepts any array data type, with automatic promotion of multiple arguments to a common data type (see Section 36.2.5).</td>
</tr>
<tr>
<td>anycompatiblenonarray</td>
<td>Indicates that a function accepts any non-array data type, with automatic promotion of multiple arguments to a common data type (see Section 36.2.5).</td>
</tr>
<tr>
<td>anycompatiblerange</td>
<td>Indicates that a function accepts any range data type, with automatic promotion of multiple arguments to a common data type (see Section 36.2.5 and Section 8.17).</td>
</tr>
<tr>
<td>anycompatiblemultirange</td>
<td>Indicates that a function accepts any multirange data type, with automatic promotion of multiple arguments to a common data type (see Section 36.2.5 and Section 8.17).</td>
</tr>
<tr>
<td>cstring</td>
<td>Indicates that a function accepts or returns a null-terminated C string.</td>
</tr>
<tr>
<td>internal</td>
<td>Indicates that a function accepts or returns a server-internal data type.</td>
</tr>
<tr>
<td>language_handler</td>
<td>A procedural language call handler is declared to return language_handler.</td>
</tr>
<tr>
<td>fdw_handler</td>
<td>A foreign-data wrapper handler is declared to return fdw_handler.</td>
</tr>
</tbody>
</table>
Functions coded in C (whether built-in or dynamically loaded) can be declared to accept or return any of these pseudo-types. It is up to the function author to ensure that the function will behave safely when a pseudo-type is used as an argument type.

Functions coded in procedural languages can use pseudo-types only as allowed by their implementation languages. At present most procedural languages forbid use of a pseudo-type as an argument type, and allow only `void` and `record` as a result type (plus `trigger` or `event_trigger` when the function is used as a trigger or event trigger). Some also support polymorphic functions using the polymorphic pseudo-types, which are shown above and discussed in detail in Section 36.2.5.

The `internal` pseudo-type is used to declare functions that are meant only to be called internally by the database system, and not by direct invocation in an SQL query. If a function has at least one `internal`-type argument then it cannot be called from SQL. To preserve the type safety of this restriction it is important to follow this coding rule: do not create any function that is declared to return `internal` unless it has at least one `internal` argument.
Chapter 9. Functions and Operators

Postgres Pro provides a large number of functions and operators for the built-in data types. This chapter describes most of them, although additional special-purpose functions appear in relevant sections of the manual. Users can also define their own functions and operators, as described in Part V. The psql commands \df and \do can be used to list all available functions and operators, respectively.

The notation used throughout this chapter to describe the argument and result data types of a function or operator is like this:

\texttt{repeat ( text, integer ) → text}

which says that the function \texttt{repeat} takes one text and one integer argument and returns a result of type text. The right arrow is also used to indicate the result of an example, thus:

\texttt{repeat('Pg', 4) → PgPgPgPg}

If you are concerned about portability then note that most of the functions and operators described in this chapter, with the exception of the most trivial arithmetic and comparison operators and some explicitly marked functions, are not specified by the SQL standard. Some of this extended functionality is present in other SQL database management systems, and in many cases this functionality is compatible and consistent between the various implementations.

9.1. Logical Operators

The usual logical operators are available:

\begin{align*}
\text{boolean AND boolean} & \rightarrow \text{boolean} \\
\text{boolean OR boolean} & \rightarrow \text{boolean} \\
\text{NOT boolean} & \rightarrow \text{boolean}
\end{align*}

SQL uses a three-valued logic system with true, false, and null, which represents “unknown”. Observe the following truth tables:

<table>
<thead>
<tr>
<th>a</th>
<th>b</th>
<th>a AND b</th>
<th>a OR b</th>
</tr>
</thead>
<tbody>
<tr>
<td>TRUE</td>
<td>TRUE</td>
<td>TRUE</td>
<td>TRUE</td>
</tr>
<tr>
<td>TRUE</td>
<td>FALSE</td>
<td>FALSE</td>
<td>TRUE</td>
</tr>
<tr>
<td>TRUE</td>
<td>NULL</td>
<td>NULL</td>
<td>TRUE</td>
</tr>
<tr>
<td>FALSE</td>
<td>FALSE</td>
<td>FALSE</td>
<td>FALSE</td>
</tr>
<tr>
<td>FALSE</td>
<td>NULL</td>
<td>FALSE</td>
<td>NULL</td>
</tr>
<tr>
<td>NULL</td>
<td>NULL</td>
<td>NULL</td>
<td>NULL</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>a</th>
<th>NOT a</th>
</tr>
</thead>
<tbody>
<tr>
<td>TRUE</td>
<td>FALSE</td>
</tr>
<tr>
<td>FALSE</td>
<td>TRUE</td>
</tr>
<tr>
<td>NULL</td>
<td>NULL</td>
</tr>
</tbody>
</table>

The operators AND and OR are commutative, that is, you can switch the left and right operands without affecting the result. (However, it is not guaranteed that the left operand is evaluated before the right operand. See Section 4.2.14 for more information about the order of evaluation of subexpressions.)

9.2. Comparison Functions and Operators

The usual comparison operators are available, as shown in Table 9.1.
### Functions and Operators

**Table 9.1. Comparison Operators**

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>datatype &lt; datatype</code> → boolean</td>
<td>Less than</td>
</tr>
<tr>
<td><code>datatype &gt; datatype</code> → boolean</td>
<td>Greater than</td>
</tr>
<tr>
<td><code>datatype &lt;= datatype</code> → boolean</td>
<td>Less than or equal to</td>
</tr>
<tr>
<td><code>datatype &gt;= datatype</code> → boolean</td>
<td>Greater than or equal to</td>
</tr>
<tr>
<td><code>datatype = datatype</code> → boolean</td>
<td>Equal</td>
</tr>
<tr>
<td><code>datatype &lt;&gt; datatype</code> → boolean</td>
<td>Not equal</td>
</tr>
<tr>
<td><code>datatype != datatype</code> → boolean</td>
<td>Not equal</td>
</tr>
</tbody>
</table>

**Note**

`<>` is the standard SQL notation for “not equal”. `!=` is an alias, which is converted to `<>` at a very early stage of parsing. Hence, it is not possible to implement `!=` and `<>` operators that do different things.

These comparison operators are available for all built-in data types that have a natural ordering, including numeric, string, and date/time types. In addition, arrays, composite types, and ranges can be compared if their component data types are comparable.

It is usually possible to compare values of related data types as well; for example `integer > bigint` will work. Some cases of this sort are implemented directly by “cross-type” comparison operators, but if no such operator is available, the parser will coerce the less-general type to the more-general type and apply the latter’s comparison operator.

As shown above, all comparison operators are binary operators that return values of type `boolean`. Thus, expressions like `1 < 2 < 3` are not valid (because there is no `<` operator to compare a Boolean value with 3). Use the `BETWEEN` predicates shown below to perform range tests.

There are also some comparison predicates, as shown in Table 9.2. These behave much like operators, but have special syntax mandated by the SQL standard.

**Table 9.2. Comparison Predicates**

<table>
<thead>
<tr>
<th>Predicate</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>datatype BETWEEN datatype AND datatype</code> → boolean</td>
<td>Between (inclusive of the range endpoints).</td>
<td>2 BETWEEN 1 AND 3 → t</td>
</tr>
<tr>
<td></td>
<td></td>
<td>2 BETWEEN 3 AND 1 → f</td>
</tr>
<tr>
<td><code>datatype NOT BETWEEN datatype AND datatype</code> → boolean</td>
<td>Not between (the negation of BETWEEN).</td>
<td>2 NOT BETWEEN 1 AND 3 → f</td>
</tr>
<tr>
<td><code>datatype BETWEEN SYMMETRIC datatype AND datatype</code> → boolean</td>
<td>Between, after sorting the two endpoint values.</td>
<td>2 BETWEEN SYMMETRIC 3 AND 1 → t</td>
</tr>
<tr>
<td><code>datatype NOT BETWEEN SYMMETRIC datatype AND datatype</code> → boolean</td>
<td>Not between, after sorting the two endpoint values.</td>
<td>2 NOT BETWEEN SYMMETRIC 3 AND 1 → f</td>
</tr>
<tr>
<td>Predicate</td>
<td>Description</td>
<td>Example(s)</td>
</tr>
<tr>
<td>-----------</td>
<td>-------------</td>
<td>------------</td>
</tr>
<tr>
<td><strong>datatype IS DISTINCT FROM datatype</strong> → boolean</td>
<td>Not equal, treating null as a comparable value.</td>
<td>1 IS DISTINCT FROM NULL → t <em>(rather than NULL)</em>&lt;br&gt;NULL IS DISTINCT FROM NULL → f <em>(rather than NULL)</em></td>
</tr>
<tr>
<td><strong>datatype IS NOT DISTINCT FROM datatype</strong> → boolean</td>
<td>Equal, treating null as a comparable value.</td>
<td>1 IS NOT DISTINCT FROM NULL → f <em>(rather than NULL)</em>&lt;br&gt;NULL IS NOT DISTINCT FROM NULL → t <em>(rather than NULL)</em></td>
</tr>
<tr>
<td><strong>datatype IS NULL</strong> → boolean</td>
<td>Test whether value is null.</td>
<td>1.5 IS NULL → f</td>
</tr>
<tr>
<td><strong>datatype IS NOT NULL</strong> → boolean</td>
<td>Test whether value is not null.</td>
<td>'null' IS NOT NULL → t</td>
</tr>
<tr>
<td><strong>datatype ISNULL</strong> → boolean</td>
<td>Test whether value is null (nonstandard syntax).</td>
<td></td>
</tr>
<tr>
<td><strong>datatype NOTNULL</strong> → boolean</td>
<td>Test whether value is not null (nonstandard syntax).</td>
<td></td>
</tr>
<tr>
<td><strong>boolean IS TRUE</strong> → boolean</td>
<td>Test whether boolean expression yields true.</td>
<td>true IS TRUE → t&lt;br&gt;NULL::boolean IS TRUE → f <em>(rather than NULL)</em></td>
</tr>
<tr>
<td><strong>boolean IS NOT TRUE</strong> → boolean</td>
<td>Test whether boolean expression yields false or unknown.</td>
<td>true IS NOT TRUE → f&lt;br&gt;NULL::boolean IS NOT TRUE → t <em>(rather than NULL)</em></td>
</tr>
<tr>
<td><strong>boolean IS FALSE</strong> → boolean</td>
<td>Test whether boolean expression yields false.</td>
<td>true IS FALSE → f&lt;br&gt;NULL::boolean IS FALSE → f <em>(rather than NULL)</em></td>
</tr>
<tr>
<td><strong>boolean IS NOT FALSE</strong> → boolean</td>
<td>Test whether boolean expression yields true or unknown.</td>
<td>true IS NOT FALSE → t&lt;br&gt;NULL::boolean IS NOT FALSE → t <em>(rather than NULL)</em></td>
</tr>
<tr>
<td><strong>boolean IS UNKNOWN</strong> → boolean</td>
<td>Test whether boolean expression yields unknown.</td>
<td>true IS UNKNOWN → f&lt;br&gt;NULL::boolean IS UNKNOWN → t <em>(rather than NULL)</em></td>
</tr>
<tr>
<td><strong>boolean IS NOT UNKNOWN</strong> → boolean</td>
<td>Test whether boolean expression yields true or false.</td>
<td>true IS NOT UNKNOWN → t&lt;br&gt;NULL::boolean IS NOT UNKNOWN → f <em>(rather than NULL)</em></td>
</tr>
</tbody>
</table>
The BETWEEN predicate simplifies range tests:

\[ a \text{ BETWEEN } x \text{ AND } y \]

is equivalent to

\[ a \geq x \text{ AND } a \leq y \]

Notice that BETWEEN treats the endpoint values as included in the range. BETWEEN SYMMETRIC is like BETWEEN except there is no requirement that the argument to the left of AND be less than or equal to the argument on the right. If it is not, those two arguments are automatically swapped, so that a nonempty range is always implied.

The various variants of BETWEEN are implemented in terms of the ordinary comparison operators, and therefore will work for any data type(s) that can be compared.

**Note**

The use of AND in the BETWEEN syntax creates an ambiguity with the use of AND as a logical operator. To resolve this, only a limited set of expression types are allowed as the second argument of a BETWEEN clause. If you need to write a more complex sub-expression in BETWEEN, write parentheses around the sub-expression.

Ordinary comparison operators yield null (signifying “unknown”), not true or false, when either input is null. For example, \( 7 = \text{NULL} \) yields null, as does \( 7 \neq \text{NULL} \). When this behavior is not suitable, use the IS [ NOT ] DISTINCT FROM predicates:

\[ a \text{ IS DISTINCT FROM } b \]
\[ a \text{ IS NOT DISTINCT FROM } b \]

For non-null inputs, IS DISTINCT FROM is the same as the <> operator. However, if both inputs are null it returns false, and if only one input is null it returns true. Similarly, IS NOT DISTINCT FROM is identical to = for non-null inputs, but it returns true when both inputs are null, and false when only one input is null. Thus, these predicates effectively act as though null were a normal data value, rather than “unknown”.

To check whether a value is or is not null, use the predicates:

expression IS NULL
expression IS NOT NULL

or the equivalent, but nonstandard, predicates:

expression ISNULL
expression NOTNULL

Do not write expression = NULL because NULL is not “equal to” NULL. (The null value represents an unknown value, and it is not known whether two unknown values are equal.)

**Tip**

Some applications might expect that expression = NULL returns true if expression evaluates to the null value. It is highly recommended that these applications be modified to comply with the SQL standard. However, if that cannot be done the transform_null_equals configuration variable is available. If it is enabled, Postgres Pro will convert \( x = \text{NULL} \) clauses to \( x \text{ IS NULL} \).

If the expression is row-valued, then IS NULL is true when the row expression itself is null or when all the row's fields are null, while IS NOT NULL is true when the row expression itself is non-null and all the row's fields are non-null. Because of this behavior, IS NULL and IS NOT NULL do not always return inverse results for row-valued expressions; in particular, a row-valued expression that contains both null and non-null fields will return false for both tests. In some cases, it may be preferable to write row IS DISTINCT FROM NULL or row IS NOT DISTINCT FROM NULL, which will simply check whether the overall row value is null without any additional tests on the row fields.
Boolean values can also be tested using the predicates

\[ boolean\_expression \ \text{IS TRUE} \]
\[ boolean\_expression \ \text{IS NOT TRUE} \]
\[ boolean\_expression \ \text{IS FALSE} \]
\[ boolean\_expression \ \text{IS NOT FALSE} \]
\[ boolean\_expression \ \text{IS UNKNOWN} \]
\[ boolean\_expression \ \text{IS NOT UNKNOWN} \]

These will always return true or false, never a null value, even when the operand is null. A null input is treated as the logical value “unknown”. Notice that \text{IS UNKNOWN} and \text{IS NOT UNKNOWN} are effectively the same as \text{IS NULL} and \text{IS NOT NULL}, respectively, except that the input expression must be of Boolean type.

Some comparison-related functions are also available, as shown in Table 9.3.

### Table 9.3. Comparison-related Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>num_nonnulls (VARIADIC &quot;any&quot;) → integer</td>
<td>Returns the number of non-null arguments.</td>
<td>num_nonnulls(1, NULL, 2) \rightarrow 2</td>
</tr>
<tr>
<td>num_nulls (VARIADIC &quot;any&quot;) → integer</td>
<td>Returns the number of null arguments.</td>
<td>num_nulls(1, NULL, 2) \rightarrow 1</td>
</tr>
</tbody>
</table>

### 9.3. Mathematical Functions and Operators

Mathematical operators are provided for many Postgres Pro types. For types without standard mathematical conventions (e.g., date/time types) we describe the actual behavior in subsequent sections.

Table 9.4 shows the mathematical operators that are available for the standard numeric types. Unless otherwise noted, operators shown as accepting \text{numeric\_type} are available for all the types \text{smallint}, \text{integer}, \text{bigint}, \text{numeric}, \text{real}, and \text{double precision}. Operators shown as accepting \text{integral\_type} are available for the types \text{smallint}, \text{integer}, and \text{bigint}. Except where noted, each form of an operator returns the same data type as its argument(s). Calls involving multiple argument data types, such as \text{integer} + \text{numeric}, are resolved by using the type appearing later in these lists.

### Table 9.4. Mathematical Operators

Table 9.5 shows the available mathematical functions. Many of these functions are provided in multiple forms with different argument types. Except where noted, any given form of a function returns the same data type as its argument(s); cross-type cases are resolved in the same way as explained above for operators. The functions working with double precision data are mostly implemented on top of the host system’s C library; accuracy and behavior in boundary cases can therefore vary depending on the host system.

### Table 9.5. Mathematical Functions

<td><code>pi()</code></td>
<td>Approximate value of π</td>
<td><code>pi() → 3.141592653589793</code></td>
</tr>
<tr>
<td><code>power()</code></td>
<td><code>a</code> raised to the power of <code>b</code></td>
<td><code>power(9, 3) → 729</code></td>
</tr>
<tr>
<td><code>radians()</code></td>
<td>Converts degrees to radians</td>
<td></td>
</tr>
</tbody>
</table>

**Note:** The table above lists some common mathematical functions and operators, along with their descriptions and example usages. The functions are available for different types of numeric values, with `numeric_type` indicating a type that includes integers, big integers, and floating point numbers.
### Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>radians(45.0)</td>
<td></td>
<td>$\rightarrow 0.7853981633974483$</td>
</tr>
<tr>
<td>round(numeric)</td>
<td>Rounds to nearest integer. For numeric, ties are broken by rounding away from zero. For double precision, the tie-breaking behavior is platform dependent, but “round to nearest even” is the most common rule.</td>
<td>$\rightarrow 42$</td>
</tr>
<tr>
<td>round(double precision)</td>
<td></td>
<td>$\rightarrow 42.4$</td>
</tr>
<tr>
<td>scale(numeric)</td>
<td>Scale of the argument (the number of decimal digits in the fractional part)</td>
<td>$\rightarrow 4$</td>
</tr>
<tr>
<td>sign(numeric)</td>
<td>Sign of the argument (-1, 0, or +1)</td>
<td>$\rightarrow -1$</td>
</tr>
<tr>
<td>sqrt(numeric)</td>
<td>Square root</td>
<td>$\rightarrow 1.4142135623730951$</td>
</tr>
<tr>
<td>trim_scale(numeric)</td>
<td>Reduces the value’s scale (number of fractional decimal digits) by removing trailing zeroes</td>
<td>$\rightarrow 8.41$</td>
</tr>
<tr>
<td>trunc(numeric)</td>
<td>Truncates to integer (towards zero)</td>
<td>$\rightarrow 42$</td>
</tr>
<tr>
<td>trunc(double precision)</td>
<td></td>
<td>$\rightarrow -42$</td>
</tr>
<tr>
<td>width_bucket(operand numeric, low numeric, high numeric, count integer)</td>
<td>Returns the number of the bucket in which operand falls in a histogram having count equal-width buckets spanning the range low to high. Returns 0 or count+1 for an input outside that range.</td>
<td>$\rightarrow 3$</td>
</tr>
</tbody>
</table>

**Note:** The thresholds array must be sorted, smallest first, or unexpected results will be obtained.
### Functions and Operators

#### Function
**Description**

- `width_bucket(now(), array['yesterday', 'today', 'tomorrow']::timestamptz[]) → 2`

### Table 9.6 shows functions for generating random numbers.

#### Table 9.6. Random Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>random()</code></td>
<td>→ double precision&lt;br&gt;Returns a random value in the range 0.0 &lt;= x &lt; 1.0</td>
<td><code>random() → 0.897124072839091</code></td>
</tr>
<tr>
<td><code>setseed(double precision)</code></td>
<td>→ void&lt;br&gt;Sets the seed for subsequent <code>random()</code> calls; argument must be between -1.0 and 1.0, inclusive</td>
<td><code>setseed(0.12345)</code></td>
</tr>
</tbody>
</table>

The `random()` function uses a simple linear congruential algorithm. It is fast but not suitable for cryptographic applications; see the `pgcrypto` module for a more secure alternative. If `setseed()` is called, the series of results of subsequent `random()` calls in the current session can be repeated by re-issuing `setseed()` with the same argument.

### Table 9.7 shows the available trigonometric functions. Each of these functions comes in two variants, one that measures angles in radians and one that measures angles in degrees.

**9.4. String Functions and Operators**

This section describes functions and operators for examining and manipulating string values. Strings in this context include values of the types `character`, `character varying`, and `text`. Except where noted, these functions and operators are declared to accept and return type `text`. They will interchangeably accept `character varying` arguments. Values of type `character` will be converted to `text` before the function or operator is applied, resulting in stripping any trailing spaces in the `character` value.

SQL defines some string functions that use key words, rather than commas, to separate arguments. Details are in **Table 9.9**. Postgres Pro also provides versions of these functions that use the regular function invocation syntax (see **Table 9.10**).

**Note**

The string concatenation operator (`||`) will accept non-string input, so long as at least one input is of string type, as shown in **Table 9.9**. For other cases, inserting an explicit coercion to `text` can be used to have non-string input accepted.

**Table 9.9. SQL String Functions and Operators**

<table>
<thead>
<tr>
<th>Function/Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>text</td>
<td></td>
<td>text</td>
</tr>
<tr>
<td>text</td>
<td></td>
<td>anynonarray</td>
</tr>
<tr>
<td>Function/Operator</td>
<td>Description</td>
<td>Example(s)</td>
</tr>
<tr>
<td>-------------------</td>
<td>-------------</td>
<td>------------</td>
</tr>
<tr>
<td><strong>Converts the non-string input to text, then concatenates the two strings.</strong></td>
<td>(The non-string input cannot be of an array type, because that would create ambiguity with the array `</td>
<td></td>
</tr>
<tr>
<td><code>text IS [NOT] [form] NORMALIZED</code></td>
<td><code>→ boolean</code></td>
<td>Checks whether the string is in the specified Unicode normalization form. The optional <code>form</code> key word specifies the form: <code>NFC</code> (the default), <code>NFD</code>, <code>NFKC</code>, or <code>NFKD</code>. This expression can only be used when the server encoding is <code>UTF8</code>. Note that checking for normalization using this expression is often faster than normalizing possibly already normalized strings.</td>
</tr>
<tr>
<td><code>bit_length (text)</code></td>
<td><code>→ integer</code></td>
<td>Returns number of bits in the string (8 times the <code>octet_length</code>).</td>
</tr>
<tr>
<td><code>char_length (text)</code></td>
<td><code>→ integer</code></td>
<td>Returns number of characters in the string.</td>
</tr>
<tr>
<td><code>lower (text)</code></td>
<td><code>→ text</code></td>
<td>Converts the string to all lower case, according to the rules of the database's locale.</td>
</tr>
<tr>
<td><code>normalize (text [, form])</code></td>
<td><code>→ text</code></td>
<td>Converts the string to the specified Unicode normalization form. The optional <code>form</code> key word specifies the form: <code>NFC</code> (the default), <code>NFD</code>, <code>NFKC</code>, or <code>NFKD</code>. This function can only be used when the server encoding is <code>UTF8</code>.</td>
</tr>
<tr>
<td><code>octet_length (text)</code></td>
<td><code>→ integer</code></td>
<td>Returns number of bytes in the string.</td>
</tr>
<tr>
<td><code>octet_length (character)</code></td>
<td><code>→ integer</code></td>
<td>Returns number of bytes in the string. Since this version of the function accepts type <code>character</code> directly, it will not strip trailing spaces.</td>
</tr>
<tr>
<td><code>overlay (string text PLACING newsubstring text FROM start integer [ FOR count integer ] )</code></td>
<td><code>→ text</code></td>
<td>Replaces the substring of <code>string</code> that starts at the <code>start</code>'th character and extends for <code>count</code> characters with <code>newsubstring</code>. If <code>count</code> is omitted, it defaults to the length of <code>newsubstring</code>.</td>
</tr>
<tr>
<td><code>position (substring text IN string text)</code></td>
<td><code>→ integer</code></td>
<td>Returns first starting index of the specified <code>substring</code> within <code>string</code>, or zero if it's not present.</td>
</tr>
<tr>
<td><code>substring (string text [ FROM start integer ][ FOR count integer ])</code></td>
<td><code>→ text</code></td>
<td>Extracts the substring of <code>string</code> starting at the <code>start</code>'th character if that is specified, and stopping after <code>count</code> characters if that is specified. Provide at least one of <code>start</code> and <code>count</code>.</td>
</tr>
<tr>
<td>Function/Operator</td>
<td>Description</td>
<td>Example(s)</td>
</tr>
<tr>
<td>------------------</td>
<td>-------------</td>
<td>------------</td>
</tr>
<tr>
<td>substring('Thomas' from 2 for 3)</td>
<td>→ hom</td>
<td></td>
</tr>
<tr>
<td>substring('Thomas' from 3)</td>
<td>→ omas</td>
<td></td>
</tr>
<tr>
<td>substring('Thomas' for 2)</td>
<td>→ Th</td>
<td></td>
</tr>
<tr>
<td>substring(string text FROM pattern text )</td>
<td>→ text</td>
<td>Extracts the first substring matching POSIX regular expression; see Section 9.7.3.</td>
</tr>
<tr>
<td>substring('Thomas' from '...$')</td>
<td>→ mas</td>
<td></td>
</tr>
<tr>
<td>substring(string text SIMILAR pattern text ESCAPE escape text )</td>
<td>→ text</td>
<td>Extracts the first substring matching SQL regular expression; see Section 9.7.2. The first form has been specified since SQL:2003; the second form was only in SQL:1999 and should be considered obsolete.</td>
</tr>
<tr>
<td>substring('Thomas' similar '%#&quot;o_a#&quot;_' escape '#')</td>
<td>→ oma</td>
<td></td>
</tr>
<tr>
<td>trim([ LEADING</td>
<td>TRAILING</td>
<td>BOTH ] [ characters text ] FROM string text )</td>
</tr>
<tr>
<td>trim(both 'xyz' from 'yxTomxx')</td>
<td>→ Tom</td>
<td></td>
</tr>
<tr>
<td>trim([ LEADING</td>
<td>TRAILING</td>
<td>BOTH ] FROM string text [, characters text ] )</td>
</tr>
<tr>
<td>trim(both from 'yxTomxx', 'xyz')</td>
<td>→ Tom</td>
<td></td>
</tr>
<tr>
<td>upper(text)</td>
<td>→ text</td>
<td>Converts the string to all upper case, according to the rules of the database's locale.</td>
</tr>
<tr>
<td>upper('tom')</td>
<td>→ TOM</td>
<td></td>
</tr>
</tbody>
</table>

Additional string manipulation functions are available and are listed in Table 9.10. Some of them are used internally to implement the SQL-standard string functions listed in Table 9.9.

### Table 9.10. Other String Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>ascii(text)</td>
<td>→ integer</td>
<td>Returns the numeric code of the first character of the argument. In UTF8 encoding, returns the Unicode code point of the character. In other multibyte encodings, the argument must be an ASCII character.</td>
</tr>
<tr>
<td>ascii('x')</td>
<td>→ 120</td>
<td></td>
</tr>
<tr>
<td>btrim(string text [, characters text ])</td>
<td>→ text</td>
<td>Removes the longest string containing only characters in characters (a space by default) from the start and end of string.</td>
</tr>
<tr>
<td>btrim('xyxtrimyyx', 'xyz')</td>
<td>→ trim</td>
<td></td>
</tr>
<tr>
<td>chr(integer)</td>
<td>→ text</td>
<td>Returns the character with the given code. In UTF8 encoding the argument is treated as a Unicode code point. In other multibyte encodings the argument must designate an ASCII character: chr(0) is disallowed because text data types cannot store that character.</td>
</tr>
<tr>
<td>chr(65)</td>
<td>→ A</td>
<td></td>
</tr>
<tr>
<td>concat(val1 &quot;any&quot; [, val2 &quot;any&quot; [, ...]])</td>
<td>→ text</td>
<td>Concatenates the text representations of all the arguments. NULL arguments are ignored.</td>
</tr>
<tr>
<td>Function</td>
<td>Description</td>
<td>Example(s)</td>
</tr>
<tr>
<td>------------</td>
<td>-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
<td>---------------------------------------------------------------------------</td>
</tr>
<tr>
<td>concat('abcde', 2, NULL, 22) → abcde222</td>
<td></td>
<td></td>
</tr>
<tr>
<td>concat_ws (sep text, val1 &quot;any&quot; [ , val2 &quot;any&quot; [ , ... ] ] ) → text</td>
<td>Concatenates all but the first argument, with separators. The first argument is used as the separator string, and should not be NULL. Other NULL arguments are ignored.</td>
<td>concat_ws(, 'abcde', 2, NULL, 22) → abcde,2,22</td>
</tr>
<tr>
<td>format ( formatstr text [ , formatarg &quot;any&quot; [ , ... ] ] ) → text</td>
<td>Formats arguments according to a format string; see Section 9.4.1. This function is similar to the C function sprintf.</td>
<td>format('Hello %s, %1$s', 'World') → Hello World, World</td>
</tr>
<tr>
<td>initcap ( text ) → text</td>
<td>Converts the first letter of each word to upper case and the rest to lower case. Words are sequences of alphanumeric characters separated by non-alphanumeric characters.</td>
<td>initcap('hi THOMAS') → Hi Thomas</td>
</tr>
<tr>
<td>left (string text, n integer) → text</td>
<td>Returns first n characters in the string, or when n is negative, returns all but last</td>
<td>n</td>
</tr>
<tr>
<td>length (text) → integer</td>
<td>Returns the number of characters in the string.</td>
<td>length('jose') → 4</td>
</tr>
<tr>
<td>lpad (string text, length integer [, fill text ] ) → text</td>
<td>Extends the string to length length by prepending the characters fill (a space by default). If the string is already longer than length then it is truncated (on the right).</td>
<td>lpad('hi', 5, 'xy') → xyxhi</td>
</tr>
<tr>
<td>ltrim (string text [, characters text ] ) → text</td>
<td>Removes the longest string containing only characters in characters (a space by default) from the start of string.</td>
<td>ltrim('zzzytest', 'xyz') → test</td>
</tr>
<tr>
<td>md5 (text) → text</td>
<td>Computes the MD5 hash of the argument, with the result written in hexadecimal.</td>
<td>md5('abc') → 900150983cd24fb0d6963f7d28e17f72</td>
</tr>
<tr>
<td>parse_ident (qualified_identifier text [, strict_mode boolean DEFAULT true ] ) → text[]</td>
<td>Splits qualified_identifier into an array of identifiers, removing any quoting of individual identifiers. By default, extra characters after the last identifier are considered an error; but if the second parameter is false, then such extra characters are ignored. (This behavior is useful for parsing names for objects like functions.) Note that this function does not truncate over-length identifiers. If you want truncation you can cast the result to name[].</td>
<td>parse_ident('&quot;SomeSchema&quot;.someTable') → {SomeSchema,sometable}</td>
</tr>
<tr>
<td>pg_client_encoding () → name</td>
<td>Returns current client encoding name.</td>
<td>pg_client_encoding() → UTF8</td>
</tr>
<tr>
<td>quote_ident (text) → text</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Function</td>
<td>Description</td>
<td>Example(s)</td>
</tr>
<tr>
<td>--------------------------</td>
<td>-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
<td>------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>quote_ident('Foo bar')</td>
<td>Returns the given string suitably quoted to be used as an identifier in an SQL statement string. Quotes are added only if necessary (i.e., if the string contains non-identifier characters or would be case-folded). Embedded quotes are properly doubled. See also Example 41.1.</td>
<td>→ &quot;Foo bar&quot;</td>
</tr>
<tr>
<td>quote_literal(text)</td>
<td>Returns the given string suitably quoted to be used as a string literal in an SQL statement string. Embedded single-quotes and backslashes are properly doubled. Note that quote_literal returns null on null input; if the argument might be null, quote_nullable is often more suitable. See also Example 41.1.</td>
<td>→ &quot;O&quot;'Reilly&quot;</td>
</tr>
<tr>
<td>quote_literal(anyelement)</td>
<td>Converts the given value to text and then quotes it as a literal. Embedded single-quotes and backslashes are properly doubled.</td>
<td>→ '42.5'</td>
</tr>
<tr>
<td>quote_nullable(text)</td>
<td>Returns the given string suitably quoted to be used as a string literal in an SQL statement string; or, if the argument is null, returns NULL. Embedded single-quotes and backslashes are properly doubled. See also Example 41.1.</td>
<td>→ NULL</td>
</tr>
<tr>
<td></td>
<td>Converts the given value to text and then quotes it as a literal; or, if the argument is null, returns NULL. Embedded single-quotes and backslashes are properly doubled.</td>
<td>→ '42.5'</td>
</tr>
<tr>
<td>regexp_match(string, pattern [, flags])</td>
<td>Returns captured substrings resulting from the first match of a POSIX regular expression to the string; see Section 9.7.3.</td>
<td>→ {bar, beque}</td>
</tr>
<tr>
<td>regexp_matches(string, pattern [, flags])</td>
<td>Returns captured substrings resulting from the first match of a POSIX regular expression to the string, or multiple matches if the g flag is used; see Section 9.7.3.</td>
<td>→</td>
</tr>
<tr>
<td></td>
<td>Replaces substrings resulting from the first match of a POSIX regular expression, or multiple substring matches if the g flag is used; see Section 9.7.3.</td>
<td>→ ThM</td>
</tr>
<tr>
<td>regexp_split_to_array(string, pattern [, flags])</td>
<td>Splits string using a POSIX regular expression as the delimiter, producing an array of results; see Section 9.7.3.</td>
<td>→ {hello, world}</td>
</tr>
<tr>
<td>regexp_split_to_table(string, pattern [, flags])</td>
<td>Splits string using a POSIX regular expression as the delimiter, producing a set of results; see Section 9.7.3.</td>
<td>→</td>
</tr>
</tbody>
</table>
### Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>hello</code></td>
<td></td>
<td></td>
</tr>
<tr>
<td><code>world</code></td>
<td></td>
<td></td>
</tr>
<tr>
<td><code>repeat</code></td>
<td>Repeats string the specified number of times.</td>
<td><code>repeat('Pg', 4) → PgPgPgPg</code></td>
</tr>
<tr>
<td><code>replace</code></td>
<td>Replaces all occurrences in string of substring from with substring to.</td>
<td><code>replace('abcdefabcdef', 'cd', 'XX') → abXXefabXXef</code></td>
</tr>
<tr>
<td><code>reverse</code></td>
<td>Reverses the order of the characters in the string.</td>
<td><code>reverse('abcde') → edcba</code></td>
</tr>
<tr>
<td><code>right</code></td>
<td>Returns last n characters in the string, or when n is negative, returns all but first</td>
<td><code>right('abcde', 2) → de</code></td>
</tr>
<tr>
<td><code>rpad</code></td>
<td>Extends the string to length length by appending the characters fill (a space by default). If the string is already longer than length then it is truncated.</td>
<td><code>rpad('hi', 5, 'xy') → hixyx</code></td>
</tr>
<tr>
<td><code>rtrim</code></td>
<td>Removes the longest string containing only characters in characters (a space by default) from the end of string.</td>
<td><code>rtrim('testxxzx', 'xyz') → test</code></td>
</tr>
<tr>
<td><code>split_part</code></td>
<td>Splits string at occurrences of delimiter and returns the n'th field (counting from one), or when n is negative, returns the</td>
<td><code>split_part('abc~@~def~@~ghi', '~@~', 2) → def</code></td>
</tr>
<tr>
<td><code>strpos</code></td>
<td>Returns first starting index of the specified substring within string, or zero if it's not present. (Same as position( substring in string), but note the reversed argument order.)</td>
<td><code>strpos('high', 'ig') → 2</code></td>
</tr>
<tr>
<td><code>substr</code></td>
<td>Extracts the substring of string starting at the start'th character, and extending for count characters if that is specified. (Same as substring( string from start for count).)</td>
<td><code>substr('alphabet', 3) → phabet</code></td>
</tr>
<tr>
<td><code>starts_with</code></td>
<td>Returns true if string starts with prefix.</td>
<td><code>starts_with('alphabet', 'alph') → t</code></td>
</tr>
</tbody>
</table>
| `string_to_array` | Splits the string at occurrences of delimiter and forms the resulting fields into a text array. If delimiter is NULL, each character in the string will become a separate element | `string_to_array(`}
<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>string_to_array</strong></td>
<td>Splits the string at occurrences of delimiter and returns the resulting fields as a set of text rows. If delimiter is NULL, each character in the string will become a separate row of the result. If delimiter is an empty string, then the string is treated as a single field. If null_string is supplied and is not NULL, fields matching that string are replaced by NULL.</td>
<td><code>string_to_array('xx~~yy~~zz', '~~', 'yy')</code> → <code>{xx,NULL,zz}</code></td>
</tr>
</tbody>
</table>

| **string_to_table** | Splits the string at occurrences of delimiter and returns the resulting fields as a set of text rows. If delimiter is NULL, each character in the string will become a separate row of the result. If delimiter is an empty string, then the string is treated as a single field. If null_string is supplied and is not NULL, fields matching that string are replaced by NULL. | `string_to_table('xx~^~yy~^~zz', '~^~', 'yy')` → `xx NULL zz` |

| **to_ascii** | Converts string to ASCII from another encoding, which may be identified by name or number. If encoding is omitted the database encoding is assumed (which in practice is the only useful case). The conversion consists primarily of dropping accents. Conversion is only supported from LATIN1, LATIN2, LATIN9, and WIN1250 encodings. (See the unaccent module for another, more flexible solution.) | `to_ascii('Karél')` → `Karel` |

| **to_hex** | Converts the number to its equivalent hexadecimal representation. | `to_hex(2147483647)` → `7fffffff` |

| **translate** | Replaces each character in string that matches a character in the from set with the corresponding character in the to set. If from is longer than to, occurrences of the extra characters in from are deleted. | `translate('12345', '143', 'ax')` → `a2x5` |

| **unistr** | Evaluate escaped Unicode characters in the argument. Unicode characters can be specified as \xxxx (4 hexadecimal digits), \+xxxxxx (6 hexadecimal digits), \uxxxx (4 hexadecimal digits), or \uxxxxxxxx (8 hexadecimal digits). To specify a backslash, write two backslashes. All other characters are taken literally. If the server encoding is not UTF-8, the Unicode code point identified by one of these escape sequences is converted to the actual server encoding; an error is reported if that's not possible. This function provides a (non-standard) alternative to string constants with Unicode escapes (see Section 4.1.2.3). | `unistr('d\0061t\+000061')` → `data` | `unistr('d\u0061t\U00000061')` → `data` |

The **concat**, **concat_ws** and **format** functions are variadic, so it is possible to pass the values to be concatenated or formatted as an array marked with the **VARIADIC** keyword (see Section 36.5.6). The array's elements are treated as if they were separate ordinary arguments to the function. If the variadic array argument is **NULL**, **concat** and **concat_ws** return **NULL**, but **format** treats a **NULL** as a zero-element array.
See also the aggregate function `string_agg` in Section 9.21, and the functions for converting between strings and the `bytea` type in Table 9.13.

### 9.4.1. format

The function `format` produces output formatted according to a format string, in a style similar to the C function `sprintf`.

```sql
format(formatstr text [, formatarg "any" [, ... ] ])
```

*formatstr* is a format string that specifies how the result should be formatted. Text in the format string is copied directly to the result, except where *format specifiers* are used. Format specifiers act as placeholders in the string, defining how subsequent function arguments should be formatted and inserted into the result. Each *formatarg* argument is converted to text according to the usual output rules for its data type, and then formatted and inserted into the result string according to the format specifier(s).

Format specifiers are introduced by a `%` character and have the form

```sql
%n$ [flags] [width] type
```

where the component fields are:

- **position** (optional)
  
  A string of the form `n$` where `n` is the index of the argument to print. Index 1 means the first argument after *formatstr*. If the *position* is omitted, the default is to use the next argument in sequence.

- **flags** (optional)
  
  Additional options controlling how the format specifier's output is formatted. Currently the only supported flag is a minus sign (`-`) which will cause the format specifier's output to be left-justified. This has no effect unless the *width* field is also specified.

- **width** (optional)
  
  Specifies the *minimum* number of characters to use to display the format specifier's output. The output is padded on the left or right (depending on the – flag) with spaces as needed to fill the width. A too-small width does not cause truncation of the output, but is simply ignored. The width may be specified using any of the following: a positive integer; an asterisk (`*`) to use the next function argument as the width; or a string of the form `*n$` to use the `n`th function argument as the width.

  If the width comes from a function argument, that argument is consumed before the argument that is used for the format specifier's value. If the width argument is negative, the result is left aligned (as if the – flag had been specified) within a field of length `abs(width)`.

- **type** (required)
  
  The type of format conversion to use to produce the format specifier's output. The following types are supported:
  
  - `s` formats the argument value as a simple string. A null value is treated as an empty string.
  - `I` treats the argument value as an SQL identifier, double-quoting it if necessary. It is an error for the value to be null (equivalent to `quote_ident`).
  - `L` quotes the argument value as an SQL literal. A null value is displayed as the string `NULL`, without quotes (equivalent to `quote_nullable`).

In addition to the format specifiers described above, the special sequence `%%` may be used to output a literal `%` character.

Here are some examples of the basic format conversions:

```sql
SELECT format('Hello %s', 'World');
Result: Hello World
```
Here are examples using width fields and the – flag:

SELECT format('|%10s|', 'foo');
Result: |       foo|

SELECT format('|%-10s|', 'foo');
Result: |foo       |

SELECT format('|%*s|', 10, 'foo');
Result: |       foo|

SELECT format('|%*s|', -10, 'foo');
Result: |foo       |

SELECT format('|%-*s|', 10, 'foo');
Result: |foo       |

SELECT format('|%-*s|', -10, 'foo');
Result: |foo       |

These examples show use of position fields:

SELECT format('Testing %3$s, %2$s, %1$s', 'one', 'two', 'three');
Result: Testing three, two, one

SELECT format('|%*2$s|', 'foo', 10, 'bar');
Result: |       bar|

SELECT format('|%1$*2$s|', 'foo', 10, 'bar');
Result: |       foo|

Unlike the standard C function sprintf, Postgres Pro's format function allows format specifiers with and without position fields to be mixed in the same format string. A format specifier without a position field always uses the next argument after the last argument consumed. In addition, the format function does not require all function arguments to be used in the format string. For example:

SELECT format('Testing %3$s, %2$s, %s', 'one', 'two', 'three');
Result: Testing three, two, three

The $% and $% format specifiers are particularly useful for safely constructing dynamic SQL statements. See Example 41.1.

9.5. Binary String Functions and Operators

This section describes functions and operators for examining and manipulating binary strings, that is values of type bytea. Many of these are equivalent, in purpose and syntax, to the text-string functions described in the previous section.

SQL defines some string functions that use key words, rather than commas, to separate arguments. Details are in Table 9.11. Postgres Pro also provides versions of these functions that use the regular function invocation syntax (see Table 9.12).
### Table 9.11. SQL Binary String Functions and Operators

<table>
<thead>
<tr>
<th>Function/Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>`bytea</td>
<td></td>
<td>bytea`</td>
</tr>
<tr>
<td><code>bit_length(bytea)</code></td>
<td>Returns number of bits in the binary string (8 times the <code>octet_length</code>).</td>
<td><code>bit_length('\x1234567890'::bytea) → 24</code></td>
</tr>
<tr>
<td><code>octet_length(bytea)</code></td>
<td>Returns number of bytes in the binary string.</td>
<td><code>octet_length('\x1234567890'::bytea) → 3</code></td>
</tr>
<tr>
<td><code>overlay(bytes bytea PLACING newsubstring bytea FROM start integer [ FOR count integer ] )</code></td>
<td>Replaces the substring of <code>bytes</code> that starts at the <code>start</code>'th byte and extends for <code>count</code> bytes with <code>newsubstring</code>. If <code>count</code> is omitted, it defaults to the length of <code>newsubstring</code>.</td>
<td><code>overlay('\x1234567890'::bytea placing '\002\003'::bytea from 2 for 3) → \x12020390</code></td>
</tr>
<tr>
<td><code>position(substring bytea IN bytes bytea)</code></td>
<td>Returns first starting index of the specified <code>substring</code> within <code>bytes</code>, or zero if it's not present.</td>
<td><code>position('\x5678'::bytea in '\x1234567890'::bytea) → 3</code></td>
</tr>
<tr>
<td><code>substring(bytes bytea [ FROM start integer ] [ FOR count integer ] )</code></td>
<td>Extracts the substring of <code>bytes</code> starting at the <code>start</code>'th byte if that is specified, and stopping after <code>count</code> bytes if that is specified. Provide at least one of <code>start</code> and <code>count</code>.</td>
<td><code>substring('\x1234567890'::bytea from 3 for 2) → \x5678</code></td>
</tr>
<tr>
<td>`trim([ LEADING</td>
<td>TRAILING</td>
<td>BOTH ] bytesremoved bytea FROM bytes bytea)`</td>
</tr>
<tr>
<td>`trim([ LEADING</td>
<td>TRAILING</td>
<td>BOTH ] [ FROM ] bytes bytea, bytesremoved bytea)`</td>
</tr>
</tbody>
</table>

Additional binary string manipulation functions are available and are listed in Table 9.12. Some of them are used internally to implement the SQL-standard string functions listed in Table 9.11.

### Table 9.12. Other Binary String Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>bit_count(bytes bytea)</code></td>
<td>Returns the number of bits set in the binary string (also known as “popcount”).</td>
<td><code>bit_count('\x1234567890'::bytea) → 15</code></td>
</tr>
<tr>
<td><code>btrim(bytes bytea, bytesremoved bytea)</code></td>
<td>Removes the longest string containing only bytes appearing in <code>bytesremoved</code> from the start and end of <code>bytes</code>.</td>
<td><code>btrim('\x1234567890'::bytea, '\x9012'::bytea) → \x345678</code></td>
</tr>
<tr>
<td>Function</td>
<td>Description</td>
<td>Example(s)</td>
</tr>
<tr>
<td>-------------------</td>
<td>-----------------------------------------------------------------------------</td>
<td>---------------------------------------------------------------------------</td>
</tr>
<tr>
<td>get_bit(bytes bytea, n bigint) → integer</td>
<td>Extracts n’th bit from binary string.</td>
<td>get_bit(’\x1234567890’::bytea, 30) → 1</td>
</tr>
<tr>
<td>get_byte(bytes bytea, n integer) → integer</td>
<td>Extracts n’th byte from binary string.</td>
<td>get_byte(’\x1234567890’::bytea, 4) → 144</td>
</tr>
<tr>
<td>length(bytea) → integer</td>
<td>Returns the number of bytes in the binary string.</td>
<td>length(’\x1234567890’::bytea) → 5</td>
</tr>
<tr>
<td>length(bytes bytea, encoding name) → integer</td>
<td>Returns the number of characters in the binary string, assuming that it is text in the given encoding.</td>
<td>length(’jose’::bytea, ’UTF8’) → 4</td>
</tr>
<tr>
<td>ltrim(bytes bytea, bytesremoved bytea) → bytea</td>
<td>Removes the longest string containing only bytes appearing in bytesremoved from the start of bytes.</td>
<td>ltrim(’\x1234567890’::bytea, ’\x9012’::bytea) → \x34567890</td>
</tr>
<tr>
<td>md5(bytea) → text</td>
<td>Computes the MD5 hash of the binary string, with the result written in hexadecimal.</td>
<td>md5(’Th\000omas’::bytea) → 8ab2d3c9689aaf18b4958c334c82d8b1</td>
</tr>
<tr>
<td>rtrim(bytes bytea, bytesremoved bytea) → bytea</td>
<td>Removes the longest string containing only bytes appearing in bytesremoved from the end of bytes.</td>
<td>rtrim(’\x1234567890’::bytea, ’\x9012’::bytea) → \x12345678</td>
</tr>
<tr>
<td>set_bit(bytes bytea, n bigint, newvalue integer) → bytea</td>
<td>Sets n’th bit in binary string to newvalue.</td>
<td>set_bit(’\x1234567890’::bytea, 30, 0) → \x1234563890</td>
</tr>
<tr>
<td>set_byte(bytes bytea, n integer, newvalue integer) → bytea</td>
<td>Sets n’th byte in binary string to newvalue.</td>
<td>set_byte(’\x1234567890’::bytea, 4, 64) → \x1234567840</td>
</tr>
<tr>
<td>sha224(bytea) → bytea</td>
<td>Computes the SHA-224 hash of the binary string.</td>
<td>sha224(’abc’::bytea) → \x23097d223405d8228642a477bda2 55b32aadbc4bda0b3f7e36c9da7</td>
</tr>
<tr>
<td>sha256(bytea) → bytea</td>
<td>Computes the SHA-256 hash of the binary string.</td>
<td>sha256(’abc’::bytea) → \xba7816bf8f01cfe414140de5dae2223 832f3b1907581bc73b00361a396177a9cb410ff61f20015ad</td>
</tr>
<tr>
<td>sha384(bytea) → bytea</td>
<td>Computes the SHA-384 hash of the binary string.</td>
<td>sha384(’abc’::bytea) → \xcdb00753f45a35e8bb5a03d699ac65007 272c32ab8ed1631a8b605a43ff5bed8086072ba1e7cc2358baeca134c825a7</td>
</tr>
<tr>
<td>sha512(bytea) → bytea</td>
<td>Computes the SHA-512 hash of the binary string.</td>
<td>sha512(bytea) → bytea</td>
</tr>
</tbody>
</table>
Function Description Example(s)

**Computes the SHA-512 hash of the binary string.**

sha512('abc'::bytea) → \xddaf35a193617abacc417349ae204131
12e6fa4e8a97eaa20a9eeee6b55d39a2192992a274fc1a836ba3c23a3feebbd
454d4423643ce80e2a9ac94fa54ca49f

**Extracts the substring of bytes starting at the start'th byte, and extending for count bytes if that is specified. (Same as substring( bytes from start for count).)**

substr('\x1234567890'::bytea, 3, 2) → \x5678

Functions get_byte and set_byte number the first byte of a binary string as byte 0. Functions get_bit and set_bit number bits from the right within each byte; for example bit 0 is the least significant bit of the first byte, and bit 15 is the most significant bit of the second byte.

For historical reasons, the function md5 returns a hex-encoded value of type text whereas the SHA-2 functions return type bytea. Use the functions encode and decode to convert between the two. For example write encode(sha256('abc'), 'hex') to get a hex-encoded text representation, or decode(md5('abc'), 'hex') to get a bytea value.

Functions for converting strings between different character sets (encodings), and for representing arbitrary binary data in textual form, are shown in Table 9.13. For these functions, an argument or result of type text is expressed in the database's default encoding, while arguments or results of type bytea are in an encoding named by another argument.

**Table 9.13. Text/Binary String Conversion Functions**

Function Description Example(s)

**convert ( bytes bytea, src_encoding name, dest_encoding name )→bytea**

Converts a binary string representing text in encoding src_encoding to a binary string in encoding dest_encoding (see Section 22.3.4 for available conversions).

convert('text_in_utf8', 'UTF8', 'LATIN1') → \x746578745f696e5f75746638

**convert_from ( bytes bytea, src_encoding name )→text**

Converts a binary string representing text in encoding src_encoding to text in the database encoding (see Section 22.3.4 for available conversions).

convert_from('text_in_utf8', 'UTF8') → text_in_utf8

**convert_to ( string text, dest_encoding name )→bytea**

Converts a text string (in the database encoding) to a binary string encoded in encoding dest_encoding (see Section 22.3.4 for available conversions).

convert_to('some_text', 'UTF8') → \x736f6d655f74657874

**encode ( byte bytea, format text )→text**

Encodes binary data into a textual representation; supported format values are: base64, escape, hex.

encode('123\000\001', 'base64') → MTIzAAE=

**decode ( string text, format text )→bytea**

Decodes binary data from a textual representation; supported format values are the same as for encode.

decode('MTIzAAE=', 'base64') → \x3132330001

The encode and decode functions support the following textual formats:
Functions and Operators

base64

The base64 format is that of RFC 2045 Section 6.8. As per the RFC, encoded lines are broken at 76 characters. However instead of the MIME CRLF end-of-line marker, only a newline is used for end-of-line. The decode function ignores carriage-return, newline, space, and tab characters. Otherwise, an error is raised when decode is supplied invalid base64 data — including when trailing padding is incorrect.

escape

The escape format converts zero bytes and bytes with the high bit set into octal escape sequences (\nnn), and it doubles backslashes. Other byte values are represented literally. The decode function will raise an error if a backslash is not followed by either a second backslash or three octal digits; it accepts other byte values unchanged.

hex

The hex format represents each 4 bits of data as one hexadecimal digit, 0 through f, writing the higher-order digit of each byte first. The encode function outputs the a-f hex digits in lower case. Because the smallest unit of data is 8 bits, there are always an even number of characters returned by encode. The decode function accepts the a-f characters in either upper or lower case. An error is raised when decode is given invalid hex data — including when given an odd number of characters.

See also the aggregate function string_agg in Section 9.21 and the large object functions in Section 33.4.

9.6. Bit String Functions and Operators

This section describes functions and operators for examining and manipulating bit strings, that is values of the types bit and bit varying. (While only type bit is mentioned in these tables, values of type bit varying can be used interchangeably.) Bit strings support the usual comparison operators shown in Table 9.1, as well as the operators shown in Table 9.14.

Table 9.14. Bit String Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>bit</td>
<td></td>
<td>bit → bit</td>
</tr>
<tr>
<td></td>
<td></td>
<td>B'10001'</td>
</tr>
<tr>
<td>bit &amp; bit → bit</td>
<td>Bitwise AND (inputs must be of equal length)</td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td>B'10001' &amp; B'01101' → 00001</td>
</tr>
<tr>
<td>bit</td>
<td>bit → bit</td>
<td>Bitwise OR (inputs must be of equal length)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>B'10001'</td>
</tr>
<tr>
<td>bit # bit → bit</td>
<td>Bitwise exclusive OR (inputs must be of equal length)</td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td>B'10001' # B'01101' → 11100</td>
</tr>
<tr>
<td>~ bit → bit</td>
<td>Bitwise NOT</td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td>~ B'10001' → 01110</td>
</tr>
<tr>
<td>bit &lt;&lt; integer → bit</td>
<td>Bitwise shift left (string length is preserved)</td>
<td></td>
</tr>
</tbody>
</table>
### Functions and Operators

#### Operator

<table>
<thead>
<tr>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>B'10001' &lt;&lt; 3</td>
<td>01000</td>
</tr>
<tr>
<td>bit &gt;&gt; integer → bit</td>
<td>Bitwise shift right (string length is preserved)</td>
</tr>
<tr>
<td>B'10001' &gt;&gt; 2</td>
<td>00100</td>
</tr>
</tbody>
</table>

Some of the functions available for binary strings are also available for bit strings, as shown in Table 9.15.

#### Table 9.15. Bit String Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>bit_count (bit) → bigint</td>
<td>Returns the number of bits set in the bit string (also known as “popcount”).</td>
<td>bit_count(B'10111') → 4</td>
</tr>
<tr>
<td>bit_length (bit) → integer</td>
<td>Returns number of bits in the bit string.</td>
<td>bit_length(B'10111') → 5</td>
</tr>
<tr>
<td>length (bit) → integer</td>
<td>Returns number of bits in the bit string.</td>
<td>length(B'10111') → 5</td>
</tr>
<tr>
<td>octet_length (bit) → integer</td>
<td>Returns number of bytes in the bit string.</td>
<td>octet_length(B'1011111011') → 2</td>
</tr>
<tr>
<td>overlay (bits bit PLACING newsubstring bit FROM start integer [ FOR count integer ]) → bit</td>
<td>Replaces the substring of bits that starts at the start'th bit and extends for count bits with newsubstring. If count is omitted, it defaults to the length of newsubstring.</td>
<td>overlay(B'01010101010101010' placing B'11111' from 2 for 3) → 0111110101010101010</td>
</tr>
<tr>
<td>position (substring bit IN bits bit) → integer</td>
<td>Returns first starting index of the specified substring within bits, or zero if it's not present.</td>
<td>position(B'010' in B'000001101011') → 8</td>
</tr>
<tr>
<td>substring (bits bit [ FROM start integer ] [ FOR count integer ]) → bit</td>
<td>Extracts the substring of bits starting at the start'th bit if that is specified, and stopping after count bits if that is specified. Provide at least one of start and count.</td>
<td>substring(B'110010111111' from 3 for 2) → 00</td>
</tr>
<tr>
<td>get_bit (bits bit, n integer) → integer</td>
<td>Extracts n'th bit from bit string; the first (leftmost) bit is bit 0.</td>
<td>get_bit(B'101010101010101010', 6) → 1</td>
</tr>
<tr>
<td>set_bit (bits bit, n integer, newvalue integer) → bit</td>
<td>Sets n'th bit in bit string to newvalue; the first (leftmost) bit is bit 0.</td>
<td>set_bit(B'101010101010101010', 6, 0) → 101010001010101010</td>
</tr>
</tbody>
</table>

In addition, it is possible to cast integral values to and from type bit. Casting an integer to bit(n) copies the rightmost n bits. Casting an integer to a bit string width wider than the integer itself will sign-extend on the left. Some examples:
Functions and Operators

44::bit(10) 0000101100
44::bit(3) 100
cast(-44 as bit(12)) 11111010100
'1110'::bit(4)::integer 14

Note that casting to just “bit” means casting to bit(1), and so will deliver only the least significant bit of the integer.

9.7. Pattern Matching

There are three separate approaches to pattern matching provided by Postgres Pro: the traditional SQL LIKE operator, the more recent SIMILAR TO operator (added in SQL:1999), and POSIX-style regular expressions. Aside from the basic “does this string match this pattern?” operators, functions are available to extract or replace matching substrings and to split a string at matching locations.

Tip

If you have pattern matching needs that go beyond this, consider writing a user-defined function in Perl or Tcl.

Caution

While most regular-expression searches can be executed very quickly, regular expressions can be contrived that take arbitrary amounts of time and memory to process. Be wary of accepting regular-expression search patterns from hostile sources. If you must do so, it is advisable to impose a statement timeout.

Searches using SIMILAR TO patterns have the same security hazards, since SIMILAR TO provides many of the same capabilities as POSIX-style regular expressions.

LIKE searches, being much simpler than the other two options, are safer to use with possibly-hostile pattern sources.

The pattern matching operators of all three kinds do not support nondeterministic collations. If required, apply a different collation to the expression to work around this limitation.

9.7.1. LIKE

string LIKE pattern [ESCAPE escape-character]
string NOT LIKE pattern [ESCAPE escape-character]

The LIKE expression returns true if the string matches the supplied pattern. (As expected, the NOT LIKE expression returns false if LIKE returns true, and vice versa. An equivalent expression is NOT (string LIKE pattern).)

If pattern does not contain percent signs or underscores, then the pattern only represents the string itself; in that case LIKE acts like the equals operator. An underscore (_) in pattern stands for (matches) any single character; a percent sign (%) matches any sequence of zero or more characters.

Some examples:

'abc' LIKE 'abc' true
'abc' LIKE 'a%' true
'abc' LIKE '_b_' true
'abc' LIKE 'c' false

LIKE pattern matching always covers the entire string. Therefore, if it's desired to match a sequence anywhere within a string, the pattern must start and end with a percent sign.
To match a literal underscore or percent sign without matching other characters, the respective character in pattern must be preceded by the escape character. The default escape character is the backslash but a different one can be selected by using the escape clause. To match the escape character itself, write two escape characters.

```
Note
If you have standard_conforming_strings turned off, any backslashes you write in literal string constants will need to be doubled. See Section 4.1.2.1 for more information.
```

It's also possible to select no escape character by writing escape ''. This effectively disables the escape mechanism, which makes it impossible to turn off the special meaning of underscore and percent signs in the pattern.

According to the SQL standard, omitting escape means there is no escape character (rather than defaulting to a backslash), and a zero-length escape value is disallowed. PostgreSQL's behavior in this regard is therefore slightly nonstandard.

The key word ILIKE can be used instead of LIKE to make the match case-insensitive according to the active locale. This is not in the SQL standard but is a Postgres Pro extension.

The operator ~~ is equivalent to LIKE, and ~~~ corresponds to ILIKE. There are also !~~ and !~~* operators that represent NOT LIKE and NOT ILIKE, respectively. All of these operators are Postgres Pro-specific. You may see these operator names in EXPLAIN output and similar places, since the parser actually translates LIKE et al. to these operators.

The phrases LIKE, ILIKE, NOT LIKE, and NOT ILIKE are generally treated as operators in Postgres Pro syntax; for example they can be used in expression operator ANY (subquery) constructs, although an escape clause cannot be included there. In some obscure cases it may be necessary to use the underlying operator names instead.

Also see the prefix operator ^@ and corresponding starts_with function, which are useful in cases where simply matching the beginning of a string is needed.

### 9.7.2. SIMILAR TO Regular Expressions

```
string SIMILAR TO pattern [ESCAPE escape-character]
string NOT SIMILAR TO pattern [ESCAPE escape-character]
```

The SIMILAR TO operator returns true or false depending on whether its pattern matches the given string. It is similar to LIKE, except that it interprets the pattern using the SQL standard's definition of a regular expression. SQL regular expressions are a curious cross between LIKE notation and common (POSIX) regular expression notation.

Like LIKE, the SIMILAR TO operator succeeds only if its pattern matches the entire string; this is unlike common regular expression behavior where the pattern can match any part of the string. Also like LIKE, SIMILAR TO uses _ and % as wildcard characters denoting any single character and any string, respectively (these are comparable to . and .* in POSIX regular expressions).

In addition to these facilities borrowed from LIKE, SIMILAR TO supports these pattern-matching metacharacters borrowed from POSIX regular expressions:

- | denotes alternation (either of two alternatives).
- * denotes repetition of the previous item zero or more times.
- + denotes repetition of the previous item one or more times.
- ? denotes repetition of the previous item zero or one time.
- {m} denotes repetition of the previous item exactly m times.
• \{m,\} denotes repetition of the previous item \(m\) or more times.
• \{m, n\} denotes repetition of the previous item at least \(m\) and not more than \(n\) times.
• Parentheses () can be used to group items into a single logical item.
• A bracket expression \([\ldots]\) specifies a character class, just as in POSIX regular expressions.

Notice that the period (.) is not a metacharacter for SIMILAR TO.

As with LIKE, a backslash disables the special meaning of any of these metacharacters. A different escape character can be specified with ESCAPE, or the escape capability can be disabled by writing ESCAPE ' '.

According to the SQL standard, omitting ESCAPE means there is no escape character (rather than defaulting to a backslash), and a zero-length ESCAPE value is disallowed. PostgreSQL’s behavior in this regard is therefore slightly nonstandard.

Another nonstandard extension is that following the escape character with a letter or digit provides access to the escape sequences defined for POSIX regular expressions; see Table 9.20, Table 9.21, and Table 9.22 below.

Some examples:

<table>
<thead>
<tr>
<th>Pattern</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>'abc' SIMILAR TO 'abc'</td>
<td>true</td>
</tr>
<tr>
<td>'abc' SIMILAR TO 'a'</td>
<td>false</td>
</tr>
<tr>
<td>'abc' SIMILAR TO '%(b</td>
<td>d)%'</td>
</tr>
<tr>
<td>'abc' SIMILAR TO '(b</td>
<td>c)%'</td>
</tr>
<tr>
<td>'-abc-' SIMILAR TO '%\mabc\M%'</td>
<td>true</td>
</tr>
<tr>
<td>'xabcy' SIMILAR TO '%\mabc\M%'</td>
<td>false</td>
</tr>
</tbody>
</table>

The substring function with three parameters provides extraction of a substring that matches an SQL regular expression pattern. The function can be written according to standard SQL syntax:

\[
\text{substring(string similar pattern escape escape-character)}
\]

or using the now obsolete SQL:1999 syntax:

\[
\text{substring(string from pattern for escape-character)}
\]

or as a plain three-argument function:

\[
\text{substring(string, pattern, escape-character)}
\]

As with SIMILAR TO, the specified pattern must match the entire data string, or else the function fails and returns null. To indicate the part of the pattern for which the matching data sub-string is of interest, the pattern should contain two occurrences of the escape character followed by a double quote ("). The text matching the portion of the pattern between these separators is returned when the match is successful.

The escape-double-quote separators actually divide substring's pattern into three independent regular expressions; for example, a vertical bar (|) in any of the three sections affects only that section. Also, the first and third of these regular expressions are defined to match the smallest possible amount of text, not the largest, when there is any ambiguity about how much of the data string matches which pattern. (In POSIX parlance, the first and third regular expressions are forced to be non-greedy.)

As an extension to the SQL standard, Postgres Pro allows there to be just one escape-double-quote separator, in which case the third regular expression is taken as empty; or no separators, in which case the first and third regular expressions are taken as empty.

Some examples, with "" delimiting the return string:

<table>
<thead>
<tr>
<th>Pattern</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>substring('foobar' similar '%&quot;o_b&quot;%' escape '&quot;')</td>
<td>oob</td>
</tr>
<tr>
<td>substring('foobar' similar '&quot;o_b&quot;%' escape '&quot;')</td>
<td>NULL</td>
</tr>
</tbody>
</table>

### 9.7.3. POSIX Regular Expressions

Table 9.16 lists the available operators for pattern matching using POSIX regular expressions.
Table 9.16. Regular Expression Match Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>text ~ text → boolean</td>
<td>String matches regular expression, case sensitively</td>
<td>'thomas' ~ 't.*ma' → t</td>
</tr>
<tr>
<td>text ~* text → boolean</td>
<td>String matches regular expression, case insensitively</td>
<td>'thomas' ~* 'T.*ma' → t</td>
</tr>
<tr>
<td>text !~ text → boolean</td>
<td>String does not match regular expression, case sensitively</td>
<td>'thomas' !~ 't.*ma' → t</td>
</tr>
<tr>
<td>text !~* text → boolean</td>
<td>String does not match regular expression, case insensitively</td>
<td>'thomas' !~* 'T.*ma' → f</td>
</tr>
</tbody>
</table>

POSIX regular expressions provide a more powerful means for pattern matching than the LIKE and SIMILAR TO operators. Many Unix tools such as egrep, sed, or awk use a pattern matching language that is similar to the one described here.

A regular expression is a character sequence that is an abbreviated definition of a set of strings (a regular set). A string is said to match a regular expression if it is a member of the regular set described by the regular expression. As with LIKE, pattern characters match string characters exactly unless they are special characters in the regular expression language — but regular expressions use different special characters than LIKE does. Unlike LIKE patterns, a regular expression is allowed to match anywhere within a string, unless the regular expression is explicitly anchored to the beginning or end of the string.

Some examples:

- 'abcd' ~ 'bc'   → true
- 'abcd' ~ 'a.c'  → true — dot matches any character
- 'abcd' ~ 'a.*d' → true — * repeats the preceding pattern item
- 'abcd' ~ '(b|x)' → true — | means OR, parentheses group
- 'abcd' ~ '^a'   → true — ^ anchors to start of string
- 'abcd' ~ '^a'   → false — would match except for anchoring

The POSIX pattern language is described in much greater detail below.

The substring function with two parameters, substring(string from pattern), provides extraction of a substring that matches a POSIX regular expression pattern. It returns null if there is no match, otherwise the first portion of the text that matched the pattern. But if the pattern contains any parentheses, the portion of the text that matched the first parenthesized subexpression (the one whose left parenthesis comes first) is returned. You can put parentheses around the whole expression if you want to use parentheses within it without triggering this exception. If you need parentheses in the pattern before the subexpression you want to extract, see the non-capturing parentheses described below.

Some examples:

substring('foobar' from 'o.b')   → oob
substring('foobar' from 'o(.)b') → o

The regexp_replace function provides substitution of new text for substrings that match POSIX regular expression patterns. It has the syntax regexp_replace(source, pattern, replacement [, flags ]). The source string is returned unchanged if there is no match to the pattern. If there is a match, the source
Functions and Operators

string is returned with the replacement string substituted for the matching substring. The replacement string can contain \n, where n is 1 through 9, to indicate that the source substring matching the n'th parenthesized subexpression of the pattern should be inserted, and it can contain \s to indicate that the substring matching the entire pattern should be inserted. Write \ if you need to put a literal backslash in the replacement text. The flags parameter is an optional text string containing zero or more single-letter flags that change the function's behavior. Flag i specifies case-insensitive matching, while flag g specifies replacement of each matching substring rather than only the first one. Supported flags (though not g) are described in Table 9.24.

Some examples:

```sql
regexp_replace('foobarbaz', 'b..', 'X')
fooXbaz
regexp_replace('foobarbaz', 'b..', 'X', 'g')
fooXX
regexp_replace('foobarbaz', 'b(..)', 'X\1Y', 'g')
fooXarYXazY
```

The `regexp_match` function returns a text array of captured substring(s) resulting from the first match of a POSIX regular expression pattern to a string. It has the syntax `regexp_match(string, pattern [, flags ])`. If there is no match, the result is NULL. If a match is found, and the pattern contains no parenthesized subexpressions, then the result is a single-element text array containing the substring matching the whole pattern. If a match is found, and the pattern contains parenthesized subexpressions, then the result is a text array whose n'th element is the substring matching the n'th parenthesized subexpression of the pattern (not counting “non-capturing” parentheses; see below for details). The flags parameter is an optional text string containing zero or more single-letter flags that change the function's behavior. Supported flags are described in Table 9.24.

Some examples:

```sql
SELECT regexp_match('foobarbequebaz', 'bar.*que');
---- regexp_match
{barbeque}
(1 row)

SELECT regexp_match('foobarbequebaz', '(bar){beque}');
---- regexp_match
{bar, beque}
(1 row)
```

In the common case where you just want the whole matching substring or NULL for no match, write something like

```sql
SELECT (regexp_match('foobarbequebaz', 'bar.*que'))[1];
--- regexp_match
barbeque
(1 row)
```

The `regexp_matches` function returns a set of text arrays of captured substring(s) resulting from matching a POSIX regular expression pattern to a string. It has the same syntax as `regexp_match`. This function returns no rows if there is no match, one row if there is a match and the g flag is not given, or N rows if there are N matches and the g flag is given. Each returned row is a text array containing the whole matched substring or the substrings matching parenthesized subexpressions of the pattern, just as described above for `regexp_match`. `regexp_matches` accepts all the flags shown in Table 9.24, plus the g flag which commands it to return all matches, not just the first one.

Some examples:
functions and operators

SELECT regexp_matches('foo', 'not there');

regexp_matches
----------------
(0 rows)

SELECT regexp_matches('foobarbequebazilbarfbonk', '(b[^b]+)(b[^b]+)', 'g');

regexp_matches
----------------
{bar,beque}
{bazil,barf}
(2 rows)

Tip

In most cases regexp_matches() should be used with the g flag, since if you only want the first match, it's easier and more efficient to use regexp_match(). However, regexp_match() only exists in Postgres Pro version 10 and up. When working in older versions, a common trick is to place a regexp_matches() call in a sub-select, for example:

SELECT col1, (SELECT regexp_matches(col2, '(bar)(beque)')) FROM tab;

This produces a text array if there's a match, or NULL if not, the same as regexp_match() would do. Without the sub-select, this query would produce no output at all for table rows without a match, which is typically not the desired behavior.

The regexp_split_to_table function splits a string using a POSIX regular expression pattern as a delimiter. It has the syntax `regexp_split_to_table(string, pattern [, flags])`. If there is no match to the pattern, the function returns the string. If there is at least one match, for each match it returns the text from the end of the last match (or the beginning of the string) to the beginning of the match. When there are no more matches, it returns the text from the end of the last match to the end of the string. The flags parameter is an optional text string containing zero or more single-letter flags that change the function's behavior. regexp_split_to_table supports the flags described in Table 9.24.

The `regexp_split_to_array` function behaves the same as `regexp_split_to_table`, except that `regexp_split_to_array` returns its result as an array of text. It has the syntax `regexp_split_to_array(string, pattern [, flags])`. The parameters are the same as for `regexp_split_to_table`.

Some examples:

SELECT foo FROM regexp_split_to_table('the quick brown fox jumps over the lazy dog', '\s+') AS foo;

foo
------
the
quick
brown
fox
jumps
over
the
lazy
dog
(9 rows)

SELECT regexp_split_to_array('the quick brown fox jumps over the lazy dog', '\s+');

regexp_split_to_array
----------------------
211

211
As the last example demonstrates, the regexp split functions ignore zero-length matches that occur at the start or end of the string or immediately after a previous match. This is contrary to the strict definition of regexp matching that is implemented by \texttt{regexp\_match} and \texttt{regexp\_matches}, but is usually the most convenient behavior in practice. Other software systems such as Perl use similar definitions.

### 9.7.3.1. Regular Expression Details

Postgres Pro's regular expressions are implemented using a software package written by Henry Spencer. Much of the description of regular expressions below is copied verbatim from his manual.

Regular expressions (REs), as defined in POSIX 1003.2, come in two forms: \textit{extended} REs or EREs (roughly those of \textit{egrep}), and \textit{basic} REs or BREs (roughly those of \textit{ed}). Postgres Pro supports both forms, and also implements some extensions that are not in the POSIX standard, but have become widely used due to their availability in programming languages such as Perl and Tcl. REs using these non-POSIX extensions are called \textit{advanced} REs or AREs in this documentation. AREs are almost an exact superset of EREs, but BREs have several notational incompatibilities (as well as being much more limited). We first describe the ARE andERE forms, noting features that apply only to AREs, and then describe how BREs differ.

---

**Note**

Postgres Pro always initially presumes that a regular expression follows the ARE rules. However, the more limited ERE or BRE rules can be chosen by prepending an \textit{embedded option} to the RE pattern, as described in Section 9.7.3.4. This can be useful for compatibility with applications that expect exactly the POSIX 1003.2 rules.

---

A regular expression is defined as one or more \textit{branches}, separated by |. It matches anything that matches one of the branches.

A branch is zero or more \textit{quantified atoms} or \textit{constraints}, concatenated. It matches a match for the first, followed by a match for the second, etc; an empty branch matches the empty string.

A quantified atom is an \textit{atom} possibly followed by a single \textit{quantifier}. Without a quantifier, it matches a match for the atom. With a quantifier, it can match some number of matches of the atom. An \textit{atom} can
be any of the possibilities shown in Table 9.17. The possible quantifiers and their meanings are shown in Table 9.18.

A constraint matches an empty string, but matches only when specific conditions are met. A constraint can be used where an atom could be used, except it cannot be followed by a quantifier. The simple constraints are shown in Table 9.19; some more constraints are described later.

**Table 9.17. Regular Expression Atoms**

<table>
<thead>
<tr>
<th>Atom</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>( re)</td>
<td>(where re is any regular expression) matches a match for re, with the match noted for possible reporting</td>
</tr>
<tr>
<td>(?: re)</td>
<td>as above, but the match is not noted for reporting (a “non-capturing” set of parentheses) (AREs only)</td>
</tr>
<tr>
<td>.</td>
<td>matches any single character</td>
</tr>
<tr>
<td>[chars]</td>
<td>a bracket expression, matching any one of the chars (see Section 9.7.3.2 for more detail)</td>
</tr>
<tr>
<td>\k</td>
<td>(where k is a non-alphanumeric character) matches that character taken as an ordinary character, e.g., \ matches a backslash character</td>
</tr>
<tr>
<td>\c</td>
<td>where c is alphanumeric (possibly followed by other characters) is an escape, see Section 9.7.3.3 (AREs only; in EREs and BREs, this matches c)</td>
</tr>
<tr>
<td>{ }</td>
<td>when followed by a character other than a digit, matches the left-brace character ; when followed by a digit, it is the beginning of a bound (see below)</td>
</tr>
<tr>
<td>x</td>
<td>where x is a single character with no other significance, matches that character</td>
</tr>
</tbody>
</table>

An RE cannot end with a backslash (\).

**Note**

If you have standard_conforming_strings turned off, any backslashes you write in literal string constants will need to be doubled. See Section 4.1.2.1 for more information.

**Table 9.18. Regular Expression Quantifiers**

<table>
<thead>
<tr>
<th>Quantifier</th>
<th>Matches</th>
</tr>
</thead>
<tbody>
<tr>
<td>*</td>
<td>a sequence of 0 or more matches of the atom</td>
</tr>
<tr>
<td>+</td>
<td>a sequence of 1 or more matches of the atom</td>
</tr>
<tr>
<td>?</td>
<td>a sequence of 0 or 1 matches of the atom</td>
</tr>
<tr>
<td>{m}</td>
<td>a sequence of exactly m matches of the atom</td>
</tr>
<tr>
<td>{m, }</td>
<td>a sequence of m or more matches of the atom</td>
</tr>
<tr>
<td>{m, n}</td>
<td>a sequence of m through n (inclusive) matches of the atom; m cannot exceed n</td>
</tr>
<tr>
<td>*?</td>
<td>non-greedy version of *</td>
</tr>
<tr>
<td>+?</td>
<td>non-greedy version of +</td>
</tr>
</tbody>
</table>
The forms using {...} are known as *bounds*. The numbers $m$ and $n$ within a bound are unsigned decimal integers with permissible values from 0 to 255 inclusive.

*Non-greedy* quantifiers (available in AREs only) match the same possibilities as their corresponding normal (greedy) counterparts, but prefer the smallest number rather than the largest number of matches. See Section 9.7.3.5 for more detail.

**Note**

A quantifier cannot immediately follow another quantifier, e.g., **** is invalid. A quantifier cannot begin an expression or subexpression or follow ^ or |.

### Table 9.19. Regular Expression Constraints

<table>
<thead>
<tr>
<th>Constraint</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>^</td>
<td>matches at the beginning of the string</td>
</tr>
<tr>
<td>$</td>
<td>matches at the end of the string</td>
</tr>
<tr>
<td>(?! re)</td>
<td><em>negative lookahead</em> matches at any point where no substring matching <em>re</em> begins (AREs only)</td>
</tr>
<tr>
<td>(?&lt;= re)</td>
<td><em>positive lookbehind</em> matches at any point where a substring matching <em>re</em> ends (AREs only)</td>
</tr>
<tr>
<td>(?!= re)</td>
<td><em>negative lookbehind</em> matches at any point where no substring matching <em>re</em> ends (AREs only)</td>
</tr>
</tbody>
</table>

Lookahead and lookbehind constraints cannot contain *back references* (see Section 9.7.3.3), and all parentheses within them are considered non-capturing.

### 9.7.3.2. Bracket Expressions

A *bracket expression* is a list of characters enclosed in [ ]. It normally matches any single character from the list (but see below). If the list begins with ^, it matches any single character not from the rest of the list. If two characters in the list are separated by −, this is shorthand for the full range of characters between those two (inclusive) in the collating sequence, e.g., [0–9] in ASCII matches any decimal digit. It is illegal for two ranges to share an endpoint, e.g., a–c–e. Ranges are very collating-sequence-dependent, so portable programs should avoid relying on them.

To include a literal ] in the list, make it the first character (after ^, if that is used). To include a literal -, make it the first or last character, or the second endpoint of a range. To use a literal − as the first endpoint of a range, enclose it in [ . and .] to make it a collating element (see below). With the exception of these characters, some combinations using [ (see next paragraphs), and escapes (AREs only), all other special characters lose their special significance within a bracket expression. In particular, \ is not special when following ERE or BRE rules, though it is special (as introducing an escape) in AREs.

Within a bracket expression, a collating element (a character, a multiple-character sequence that collates as if it were a single character, or a collating-sequence name for either) enclosed in [ . and .] stands for the sequence of characters of that collating element. The sequence is treated as a single element of
the bracket expression's list. This allows a bracket expression containing a multiple-character collating
element to match more than one character, e.g., if the collating sequence includes a ch collating element,
then the RE \([\{.\}.ch.]\)*c matches the first five characters of chchcc.

**Note**

Postgres Pro currently does not support multi-character collating elements. This information
describes possible future behavior.

Within a bracket expression, a collating element enclosed in \([= and =]\) is an **equivalence class**, standing
for the sequences of characters of all collating elements equivalent to that one, including itself. (If there
are no other equivalent collating elements, the treatment is as if the enclosing delimiters were \( . \) and
\( . \).) For example, if \( a \) and \( ^ \) are the members of an equivalence class, then \( [[=o=]], [[=^=]], \) and \( [o^] \)
are all synonymous. An equivalence class cannot be an endpoint of a range.

Within a bracket expression, the name of a character class enclosed in \([: and :]\) stands for the list of all
characters belonging to that class. A character class cannot be used as an endpoint of a range. The POSIX
standard defines these character class names: **alnum** (letters and numeric digits), **alpha** (letters), **blank**
(space and tab), **cntrl** (control characters), **digit** (numeric digits), **graph** (printable characters except
space), **lower** (lower-case letters), **print** (printable characters including space), **punct** (punctuation),
**space** (any white space), **upper** (upper-case letters), and **xdigit** (hexadecimal digits). The behavior of
these standard character classes is generally consistent across platforms for characters in the 7-bit ASCII set. Whether a given non-ASCII character is considered to belong to one of these classes depends
on the **collation** that is used for the regular-expression function or operator (see Section 22.2), or by
default on the database's **LC_CTYPE** locale setting (see Section 22.1). The classification of non-ASCII
characters can vary across platforms even in similarly-named locales. (But the c locale never considers
any non-ASCII characters to belong to any of these classes.) In addition to these standard character
classes, Postgres Pro defines the **word** character class, which is the same as **alnum** plus the underscore
(\( _ \)) character, and the **ascii** character class, which contains exactly the 7-bit ASCII set.

There are two special cases of bracket expressions: the bracket expressions \([[:<:]\) and \([[:>:]]\) are
constraints, matching empty strings at the beginning and end of a word respectively. A word is defined
as a sequence of word characters that is neither preceded nor followed by word characters. A word
character is any character belonging to the **word** character class, that is, any letter, digit, or underscore.
This is an extension, compatible with but not specified by POSIX 1003.2, and should be used with caution
in software intended to be portable to other systems. The constraint escapes described below are usually
preferable; they are no more standard, but are easier to type.

### 9.7.3.3. Regular Expression Escapes

**Escapes** are special sequences beginning with \( \backslash \) followed by an alphanumeric character. Escapes come
in several varieties: character entry, class shorthands, constraint escapes, and back references. A \( \backslash \)
followed by an alphanumeric character but not constituting a valid escape is illegal in AREs. In EREs,
there are no escapes: outside a bracket expression, a \( \backslash \) followed by an alphanumeric character merely
stands for that character as an ordinary character, and inside a bracket expression, \( \backslash \) is an ordinary
character. (The latter is the one actual incompatibility between EREs and AREs.)

**Character-entry escapes** exist to make it easier to specify non-printing and other inconvenient characters
in REs. They are shown in Table 9.20.

**Class-shorthand escapes** provide shorthands for certain commonly-used character classes. They are
shown in Table 9.21.

A **constraint escape** is a constraint, matching the empty string if specific conditions are met, written as
an escape. They are shown in Table 9.22.

A **back reference** \( \( \backslash n \) \) matches the same string matched by the previous parenthesized subexpression
specified by the number \( n \) (see Table 9.23). For example, \( ([bc])\( \backslash 1 \) matches bb or cc but not bc or cb.
Functions and Operators

The subexpression must entirely precede the back reference in the RE. Subexpressions are numbered in the order of their leading parentheses. Non-capturing parentheses do not define subexpressions. The back reference considers only the string characters matched by the referenced subexpression, not any constraints contained in it. For example, (^\d)\1 will match 22.

Table 9.20. Regular Expression Character-Entry Escapes

<table>
<thead>
<tr>
<th>Escape</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\a</td>
<td>alert (bell) character, as in C</td>
</tr>
<tr>
<td>\b</td>
<td>backspace, as in C</td>
</tr>
<tr>
<td>\B</td>
<td>synonym for backslash () to help reduce the need for backslash doubling</td>
</tr>
<tr>
<td>\cX</td>
<td>(where X is any character) the character whose low-order 5 bits are the same as those of X, and whose other bits are all zero</td>
</tr>
<tr>
<td>\e</td>
<td>the character whose collating-sequence name is ESC, or failing that, the character with octal value 033</td>
</tr>
<tr>
<td>\f</td>
<td>form feed, as in C</td>
</tr>
<tr>
<td>\n</td>
<td>newline, as in C</td>
</tr>
<tr>
<td>\r</td>
<td>carriage return, as in C</td>
</tr>
<tr>
<td>\t</td>
<td>horizontal tab, as in C</td>
</tr>
<tr>
<td>\uwxyz</td>
<td>(where wxyz is exactly four hexadecimal digits) the character whose hexadecimal value is 0xwxyz</td>
</tr>
<tr>
<td>\Ustuvwxyz</td>
<td>(where stuvwxyz is exactly eight hexadecimal digits) the character whose hexadecimal value is 0xstuvwxyz</td>
</tr>
<tr>
<td>\v</td>
<td>vertical tab, as in C</td>
</tr>
<tr>
<td>\xhhh</td>
<td>(where hhh is any sequence of hexadecimal digits) the character whose hexadecimal value is 0xhhh (a single character no matter how many hexadecimal digits are used)</td>
</tr>
<tr>
<td>\0</td>
<td>the character whose value is 0 (the null byte)</td>
</tr>
<tr>
<td>\xy</td>
<td>(where xy is exactly two octal digits, and is not a back reference) the character whose octal value is 0xy</td>
</tr>
<tr>
<td>\xyz</td>
<td>(where xyz is exactly three octal digits, and is not a back reference) the character whose octal value is 0xyz</td>
</tr>
</tbody>
</table>

Hexadecimal digits are 0-9, a-f, and A-F. Octal digits are 0-7.

Numeric character-entry escapes specifying values outside the ASCII range (0-127) have meanings dependent on the database encoding. When the encoding is UTF-8, escape values are equivalent to Unicode code points, for example \u1234 means the character U+1234. For other multibyte encodings, character-entry escapes usually just specify the concatenation of the byte values for the character. If the escape value does not correspond to any legal character in the database encoding, no error will be raised, but it will never match any data.

The character-entry escapes are always taken as ordinary characters. For example, \135 is ] in ASCII, but \135 does not terminate a bracket expression.
### Table 9.21. Regular Expression Class-Shorthand Escapes

<table>
<thead>
<tr>
<th>Escape</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\d</td>
<td>matches any digit, like <code>[:digit:]</code></td>
</tr>
<tr>
<td>\s</td>
<td>matches any whitespace character, like <code>[:space:]</code></td>
</tr>
<tr>
<td>\w</td>
<td>matches any word character, like <code>[:word:]</code></td>
</tr>
<tr>
<td>\D</td>
<td>matches any non-digit, like <code>[^:digit:]</code></td>
</tr>
<tr>
<td>\S</td>
<td>matches any non-whitespace character, like <code>[^:space:]</code></td>
</tr>
<tr>
<td>\W</td>
<td>matches any non-word character, like <code>[^:word:]</code></td>
</tr>
</tbody>
</table>

The class-shorthand escapes also work within bracket expressions, although the definitions shown above are not quite syntactically valid in that context. For example, `[a-c\d]` is equivalent to `[a-c[:digit:]]`.

### Table 9.22. Regular Expression Constraint Escapes

<table>
<thead>
<tr>
<th>Escape</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\A</td>
<td>matches only at the beginning of the string (see Section 9.7.3.5 for how this differs from <code>^</code>)</td>
</tr>
<tr>
<td>\m</td>
<td>matches only at the beginning of a word</td>
</tr>
<tr>
<td>\M</td>
<td>matches only at the end of a word</td>
</tr>
<tr>
<td>\y</td>
<td>matches only at the beginning or end of a word</td>
</tr>
<tr>
<td>\Y</td>
<td>matches only at a point that is not the beginning or end of a word</td>
</tr>
<tr>
<td>\Z</td>
<td>matches only at the end of the string (see Section 9.7.3.5 for how this differs from <code>$</code>)</td>
</tr>
</tbody>
</table>

A word is defined as in the specification of `[:<:]` and `[:>:]` above. Constraint escapes are illegal within bracket expressions.

### Table 9.23. Regular Expression Back References

<table>
<thead>
<tr>
<th>Escape</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\m</td>
<td>(where ( m ) is a nonzero digit) a back reference to the ( m )th subexpression</td>
</tr>
<tr>
<td>\mnn</td>
<td>(where ( m ) is a nonzero digit, and ( nn ) is some more digits, and the decimal value ( mnn ) is not greater than the number of closing capturing parentheses seen so far) a back reference to the ( mnn )th subexpression</td>
</tr>
</tbody>
</table>

### Note

There is an inherent ambiguity between octal character-entry escapes and back references, which is resolved by the following heuristics, as hinted at above. A leading zero always indicates an octal escape. A single non-zero digit, not followed by another digit, is always taken as a back reference. A multi-digit sequence not starting with a zero is taken as a back reference if it comes after a suitable subexpression (i.e., the number is in the legal range for a back reference), and otherwise is taken as octal.
9.7.3.4. Regular Expression Metasyntax

In addition to the main syntax described above, there are some special forms and miscellaneous syntactic facilities available.

An RE can begin with one of two special director prefixes. If an RE begins with `***`, the rest of the RE is taken as an ARE. (This normally has no effect in Postgres Pro, since REs are assumed to be AREs; but it does have an effect if ERE or BRE mode had been specified by the flags parameter to a regex function.) If an RE begins with `***=`, the rest of the RE is taken to be a literal string, with all characters considered ordinary characters.

An ARE can begin with embedded options: a sequence (`(?xyz)`) (where `xyz` is one or more alphabetic characters) specifies options affecting the rest of the RE. These options override any previously determined options — in particular, they can override the case-sensitivity behavior implied by a regex operator, or the flags parameter to a regex function. The available option letters are shown in Table 9.24. Note that these same option letters are used in the flags parameters of regex functions.

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>b</td>
<td>rest of RE is a BRE</td>
</tr>
<tr>
<td>c</td>
<td>case-sensitive matching (overrides operator type)</td>
</tr>
<tr>
<td>e</td>
<td>rest of RE is an ERE</td>
</tr>
<tr>
<td>i</td>
<td>case-insensitive matching (see Section 9.7.3.5) (overrides operator type)</td>
</tr>
<tr>
<td>m</td>
<td>historical synonym for n</td>
</tr>
<tr>
<td>n</td>
<td>newline-sensitive matching (see Section 9.7.3.5)</td>
</tr>
<tr>
<td>p</td>
<td>partial newline-sensitive matching (see Section 9.7.3.5)</td>
</tr>
<tr>
<td>q</td>
<td>rest of RE is a literal (“quoted”) string, all ordinary characters</td>
</tr>
<tr>
<td>s</td>
<td>non-newline-sensitive matching (default)</td>
</tr>
<tr>
<td>t</td>
<td>tight syntax (default; see below)</td>
</tr>
<tr>
<td>w</td>
<td>inverse partial newline-sensitive (“weird”) matching (see Section 9.7.3.5)</td>
</tr>
<tr>
<td>x</td>
<td>expanded syntax (see below)</td>
</tr>
</tbody>
</table>

Embedded options take effect at the ) terminating the sequence. They can appear only at the start of an ARE (after the `***`: director if any).

In addition to the usual (tight) RE syntax, in which all characters are significant, there is an expanded syntax, available by specifying the embedded x option. In the expanded syntax, white-space characters in the RE are ignored, as are all characters between a # and the following newline (or the end of the RE). This permits paragraphing and commenting a complex RE. There are three exceptions to that basic rule:

- a white-space character or # preceded by \ is retained
- white space or # within a bracket expression is retained
- white space and comments cannot appear within multi-character symbols, such as (?:

For this purpose, white-space characters are blank, tab, newline, and any character that belongs to the space character class.

Finally, in an ARE, outside bracket expressions, the sequence (`(?#ttt)`) (where ttt is any text not containing a ) is a comment, completely ignored. Again, this is not allowed between the characters of
multi-character symbols, like (?::). Such comments are more a historical artifact than a useful facility, and their use is deprecated; use the expanded syntax instead.

None of these metasyntax extensions is available if an initial **=* director has specified that the user’s input be treated as a literal string rather than as an RE.

### 9.7.3.5. Regular Expression Matching Rules

In the event that an RE could match more than one substring of a given string, the RE matches the one starting earliest in the string. If the RE could match more than one substring starting at that point, either the longest possible match or the shortest possible match will be taken, depending on whether the RE is **greedy** or **non-greedy**.

Whether an RE is greedy or not is determined by the following rules:

- Most atoms, and all constraints, have no greediness attribute (because they cannot match variable amounts of text anyway).
- Adding parentheses around an RE does not change its greediness.
- A quantified atom with a fixed-repetition quantifier {{m} or {m}?} has the same greediness (possibly none) as the atom itself.
- A quantified atom with other normal quantifiers (including {m, n} with m equal to n) is greedy (prefers longest match).
- A quantified atom with a non-greedy quantifier (including {m, n}? with m equal to n) is non-greedy (prefers shortest match).
- A branch — that is, an RE that has no top-level | operator — has the same greediness as the first quantified atom in it that has a greediness attribute.
- An RE consisting of two or more branches connected by the | operator is always greedy.

The above rules associate greediness attributes not only with individual quantified atoms, but with branches and entire REs that contain quantified atoms. What that means is that the matching is done in such a way that the branch, or whole RE, matches the longest or shortest possible substring **as a whole**. Once the length of the entire match is determined, the part of it that matches any particular subexpression is determined on the basis of the greediness attribute of that subexpression, with subexpressions starting earlier in the RE taking priority over ones starting later.

An example of what this means:

```sql
SELECT SUBSTRING('XY1234Z', 'Y*([0-9]{1,3})');
Result: 123
```

In the first case, the RE as a whole is greedy because Y* is greedy. It can match beginning at the Y, and it matches the longest possible string starting there, i.e., Y123. The output is the parenthesized part of that, or 123.

```sql
SELECT SUBSTRING('XY1234Z', 'Y*?([0-9]{1,3})');
Result: 1
```

In the second case, the RE as a whole is non-greedy because Y*? is non-greedy. It can match beginning at the Y, and it matches the shortest possible string starting there, i.e., Y1. The subexpression [0-9]{1,3} is greedy but it cannot change the decision as to the overall match length; so it is forced to match just 1.

In short, when an RE contains both greedy and non-greedy subexpressions, the total match length is either as long as possible or as short as possible, according to the attribute assigned to the whole RE. The attributes assigned to the subexpressions only affect how much of that match they are allowed to “eat” relative to each other.

The quantifiers {1,1} and {1,1}? can be used to force greediness or non-greediness, respectively, on a subexpression or a whole RE. This is useful when you need the whole RE to have a greediness attribute different from what's deduced from its elements. As an example, suppose that we are trying to separate
a string containing some digits into the digits and the parts before and after them. We might try to do that like this:

```
SELECT regexp_match('abc01234xyz', '(.*)(\d+)(.*)');
Result: {abc01234,0,xyz}
```

That didn't work: the first .* is greedy so it "eats" as much as it can, leaving the \d+ to match at the last possible place, the last digit. We might try to fix that by making it non-greedy:

```
SELECT regexp_match('abc01234xyz', '(.*?)(\d+)(.*)');
Result: {abc,0,""}
```

That didn't work either, because now the RE as a whole is non-greedy and so it ends the overall match as soon as possible. We can get what we want by forcing the RE as a whole to be greedy:

```
SELECT regexp_match('abc01234xyz', '(?:(.*?)(\d+)(.*)){1,1}');
Result: {abc,01234,xyz}
```

Controlling the RE's overall greediness separately from its components' greediness allows great flexibility in handling variable-length patterns.

When deciding what is a longer or shorter match, match lengths are measured in characters, not collating elements. An empty string is considered longer than no match at all. For example: bb* matches the three middle characters of abbbc; (week|wee)(night|knight) matches all ten characters of weeknights; when (.*)* is matched against abc the parenthesized subexpression matches all three characters; and when (a*)* is matched against bc both the whole RE and the parenthesized subexpression match an empty string.

If case-independent matching is specified, the effect is much as if all case distinctions had vanished from the alphabet. When an alphabetic that exists in multiple cases appears as an ordinary character outside a bracket expression, it is effectively transformed into a bracket expression containing both cases, e.g., x becomes [xX]. When it appears inside a bracket expression, all case counterparts of it are added to the bracket expression, e.g., [x] becomes [xX] and [^x] becomes [^xX].

If newline-sensitive matching is specified, the effect is much as if all case distinctions had vanished from the alphabet. When an alphabetic that exists in multiple cases appears as an ordinary character outside a bracket expression, it is effectively transformed into a bracket expression containing both cases, e.g., x becomes [xX]. When it appears inside a bracket expression, all case counterparts of it are added to the bracket expression, e.g., [x] becomes [xX] and [^x] becomes [^xX].

If partial newline-sensitive matching is specified, this affects . and bracket expressions as with newline-sensitive matching, but not ^ and $.

If inverse partial newline-sensitive matching is specified, this affects ^ and $ as with newline-sensitive matching, but not . and bracket expressions. This isn't very useful but is provided for symmetry.

### 9.7.3.6. Limits and Compatibility

No particular limit is imposed on the length of REs in this implementation. However, programs intended to be highly portable should not employ REs longer than 256 bytes, as a POSIX-compliant implementation can refuse to accept such REs.

The only feature of AREs that is actually incompatible with POSIX EREs is that \ does not lose its special significance inside bracket expressions. All other ARE features use syntax which is illegal or has undefined or unspecified effects in POSIX EREs; the *** syntax of directors likewise is outside the POSIX syntax for both BREs and EREs.

Many of the ARE extensions are borrowed from Perl, but some have been changed to clean them up, and a few Perl extensions are not present. Incompatibilities of note include \b, \B, the lack of special treatment for a trailing newline, the addition of complemented bracket expressions to the
things affected by newline-sensitive matching, the restrictions on parentheses and back references in lookahead/lookbehind constraints, and the longest/shortest-match (rather than first-match) matching semantics.

9.7.3.7. Basic Regular Expressions

BREs differ from EREs in several respects. In BREs, |, +, and ? are ordinary characters and there is no equivalent for their functionality. The delimiters for bounds are \{ and \}, with { and } by themselves ordinary characters. The parentheses for nested subexpressions are \( and \), with ( and ) by themselves ordinary characters. ^ is an ordinary character except at the beginning of the RE or the beginning of a parenthesized subexpression, $ is an ordinary character except at the end of the RE or the end of a parenthesized subexpression, and * is an ordinary character if it appears at the beginning of the RE or the beginning of a parenthesized subexpression (after a possible leading "). Finally, single-digit back references are available, and < and > are synonyms for [[<:]] and [[>:]] respectively; no other escapes are available in BREs.

9.7.3.8. Differences from XQuery (LIKE_REGEX)

Since SQL:2008, the SQL standard includes a LIKE_REGEX operator that performs pattern matching according to the XQuery regular expression standard. Postgres Pro does not yet implement this operator, but you can get very similar behavior using the regexp_match() function, since XQuery regular expressions are quite close to the ARE syntax described above.

Notable differences between the existing POSIX-based regular-expression feature and XQuery regular expressions include:

- XQuery character class subtraction is not supported. An example of this feature is the following to match only English consonants: [a-z-[aeiou]].
- XQuery character class shorthands \c, \C, \i, and \I are not supported.
- XQuery character class elements using \p{UnicodeProperty} or the inverse \P{UnicodeProperty} are not supported.
- POSIX interprets character classes such as \w (see Table 9.21) according to the prevailing locale (which you can control by attaching a COLLATE clause to the operator or function). XQuery specifies these classes by reference to Unicode character properties, so equivalent behavior is obtained only with a locale that follows the Unicode rules.
- The SQL standard (not XQuery itself) attempts to cater for more variants of "newline" than POSIX does. The newline-sensitive matching options described above consider only ASCII NL (\n) to be a newline, but SQL would have us treat CR (\r), CRLF (\r\n) (a Windows-style newline), and some Unicode-only characters like LINE SEPARATOR (U+2028) as newlines as well. Notably, . and \s should count \r\n as one character not two according to SQL.
- Of the character-entry escapes described in Table 9.20, XQuery supports only \n, \r, and \t.
- XQuery does not support the [\name:] syntax for character classes within bracket expressions.
- XQuery does not have lookahead or lookbehind constraints, nor any of the constraint escapes described in Table 9.22.
- The metasyntax forms described in Section 9.7.3.4 do not exist in XQuery.
- The regular expression flag letters defined by XQuery are related to but not the same as the option letters for POSIX (Table 9.24). While the i and q options behave the same, others do not:
  - XQuery’s s (allow dot to match newline) and m (allow ^ and $ to match at newlines) flags provide access to the same behaviors as POSIX’s n, p and v flags, but they do not match the behavior of POSIX’s s and m flags. Note in particular that dot-matches-newline is the default behavior in POSIX but not XQuery.
  - XQuery’s x (ignore whitespace in pattern) flag is noticeably different from POSIX’s expanded-mode flag. POSIX’s x flag also allows # to begin a comment in the pattern, and POSIX will not ignore a whitespace character after a backslash.
9.8. Data Type Formatting Functions

The Postgres Pro formatting functions provide a powerful set of tools for converting various data types (date/time, integer, floating point, numeric) to formatted strings and for converting from formatted strings to specific data types. Table 9.25 lists them. These functions all follow a common calling convention: the first argument is the value to be formatted and the second argument is a template that defines the output or input format.

Table 9.25. Formatting Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>to_char (timestamp, text) → text</code></td>
<td>Converts time stamp to string according to the given format.</td>
<td><code>to_char(timestamp '2002-04-20 17:31:12.66', 'HH12:MI:SS') → 05:31:12</code></td>
</tr>
<tr>
<td><code>to_char (interval, text) → text</code></td>
<td>Converts interval to string according to the given format.</td>
<td><code>to_char(interval '15h 2m 12s', 'HH24:MI:SS') → 15:02:12</code></td>
</tr>
<tr>
<td><code>to_char (numeric_type, text) → text</code></td>
<td>Converts number to string according to the given format; available for <code>integer</code>, <code>bigint</code>, <code>numeric</code>, <code>real</code>, <code>double precision</code>.</td>
<td><code>to_char(125, '999') → 125</code>&lt;br&gt;<code>to_char(125.8::real, '999D9') → 125.8</code>&lt;br&gt;<code>to_char(-125.8, '999D99S') → 125.80-</code></td>
</tr>
<tr>
<td><code>to_date (text, text) → date</code></td>
<td>Converts string to date according to the given format.</td>
<td><code>to_date('05 Dec 2000', 'DD Mon YYYY') → 2000-12-05</code></td>
</tr>
<tr>
<td><code>to_number (text, text) → numeric</code></td>
<td>Converts string to numeric according to the given format.</td>
<td><code>to_number('12,454.8-', '99G999D9S') → -12454.8</code></td>
</tr>
<tr>
<td><code>to_timestamp (text, text) → timestamp with time zone</code></td>
<td>Converts string to time stamp according to the given format. (See also <code>to_timestamp(double precision)</code> in Table 9.32.)</td>
<td><code>to_timestamp('05 Dec 2000', 'DD Mon YYYY') → 2000-12-05 00:00:00-05</code></td>
</tr>
</tbody>
</table>

**Tip**

`to_timestamp` and `to_date` exist to handle input formats that cannot be converted by simple casting. For most standard date/time formats, simply casting the source string to the required data type works, and is much easier. Similarly, `to_number` is unnecessary for standard numeric representations.

In a `to_char` output template string, there are certain patterns that are recognized and replaced with appropriately-formatted data based on the given value. Any text that is not a template pattern is simply copied verbatim. Similarly, in an input template string (for the other functions), template patterns identify the values to be supplied by the input data string. If there are characters in the template string that are not template patterns, the corresponding characters in the input data string are simply skipped over (whether or not they are equal to the template string characters).
Table 9.26 shows the template patterns available for formatting date and time values.

</table>

Modifiers can be applied to any template pattern to alter its behavior. For example, FMMonth is the Month pattern with the FM modifier. Table 9.27 shows the modifier patterns for date/time formatting.
### Table 9.27. Template Pattern Modifiers for Date/Time Formatting

<table>
<thead>
<tr>
<th>Modifier</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>FM</strong> prefix</td>
<td>fill mode (suppress leading zeroes and padding blanks)</td>
<td>FMMonth</td>
</tr>

<td><strong>TH</strong> suffix</td>
<td>upper case ordinal number suffix</td>
<td>DDTH, e.g., 12TH</td>
</tr>
<tr>
<td><strong>th</strong> suffix</td>
<td>lower case ordinal number suffix</td>
<td>DDth, e.g., 12th</td>
</tr>
<tr>
<td><strong>FX</strong> prefix</td>
<td>fixed format global option (see usage notes)</td>
<td>FX Month DD Day</td>
</tr>
<tr>
<td><strong>TM</strong> prefix</td>
<td>translation mode (use localized day and month names based on lc_time)</td>
<td>TMMonth</td>
</tr>
<tr>
<td><strong>SP</strong> suffix</td>
<td>spell mode (not implemented)</td>
<td>DDSP</td>
</tr>
</tbody>
</table>

**Usage notes for date/time formatting:**

- **FM** suppresses leading zeroes and trailing blanks that would otherwise be added to make the output of a pattern be fixed-width. In Postgres Pro, **FM** modifies only the next specification, while in Oracle **FM** affects all subsequent specifications, and repeated **FM** modifiers toggle fill mode on and off.

- **TM** suppresses trailing blanks whether or not **FM** is specified.

- **to_timestamp** and **to_date** ignore letter case in the input; so for example **MON**, **Mon**, and **mon** all accept the same strings. When using the **TM** modifier, case-folding is done according to the rules of the function's input collation (see Section 22.2).

- **to_timestamp** and **to_date** skip multiple blank spaces at the beginning of the input string and around date and time values unless the **FX** option is used. For example, `to_timestamp(' 2000 JUN', 'YYYY MON') and to_timestamp('2000 - JUN', 'YYYY-MON')` work, but `to_timestamp('2000 JUN', 'FXYYYY MON')` returns an error because to_timestamp expects only a single space. **FX** must be specified as the first item in the template.

- A separator (a space or non-letter/non-digit character) in the template string of **to_timestamp** and **to_date** matches any single separator in the input string or is skipped, unless the **FX** option is used. For example, `to_timestamp('2000/JUN', 'YYYY///MON') and to_timestamp('2000/JUN', 'YYYY/MON')` work, but `to_timestamp('2000//JUN', 'YYYY/MON')` returns an error because the number of separators in the input string exceeds the number of separators in the template.

If **FX** is specified, a separator in the template string matches exactly one character in the input string. But note that the input string character is not required to be the same as the separator from the template string. For example, `to_timestamp('2000/JUN', 'FXYYYY MON')` works, but `to_timestamp('2000/JUN', 'FXYYYY  MON')` returns an error because the second space in the template string consumes the letter J from the input string.

- A **TZH** template pattern can match a signed number. Without the **FX** option, minus signs may be ambiguous, and could be interpreted as a separator. This ambiguity is resolved as follows: If the number of separators before **TZH** in the template string is less than the number of separators before the minus sign in the input string, the minus sign is interpreted as part of **TZH**. Otherwise, the minus sign is considered to be a separator between values. For example, `to_timestamp('2000-10', 'YYYY TZH') matches -10 to TZH, but to_timestamp('2000 -10', 'YYYY  TZH') matches 10 to TZH.

- Ordinary text is allowed in **to_char** templates and will be output literally. You can put a substring in double quotes to force it to be interpreted as literal text even if it contains template patterns. For example, in "'Hello Year 'YYYY", the YYYY will be replaced by the year data, but the single y in Year will not be. In **to_date**, **to_number**, and **to_timestamp**, literal text and double-quoted strings result in skipping the number of characters contained in the string; for example *"XX"* skips two input characters (whether or not they are **XX**).
Prior to Postgres Pro 12, it was possible to skip arbitrary text in the input string using non-letter or non-digit characters. For example, `to_timestamp('2000y6m1d', 'yyyy-MM-DD')` used to work. Now you can only use letter characters for this purpose. For example, `to_timestamp('2000y6m1d', 'yyyytMMtDDt')` and `to_timestamp('2000y6m1d', 'yyyy"y"MM"m"DD"d")` skip $y$, $m$, and $d$.

- If you want to have a double quote in the output you must precede it with a backslash, for example `'"YYYY Month"'`. Backslashes are not otherwise special outside of double-quoted strings. Within a double-quoted string, a backslash causes the next character to be taken literally, whatever it is (but this has no special effect unless the next character is a double quote or another backslash).

- In `to_timestamp` and `to_date`, if the year format specification is less than four digits, e.g., `YYY`, and the supplied year is less than four digits, the year will be adjusted to be nearest to the year 2020, e.g., 95 becomes 1995.

- In `to_timestamp` and `to_date`, negative years are treated as signifying BC. If you write both a negative year and an explicit BC field, you get AD again. An input of year zero is treated as 1 BC.

- In `to_timestamp` and `to_date`, if the `YYYY` conversion has a restriction when processing years with more than 4 digits. You must use some non-digit character or template after `YYYY`, otherwise the year is always interpreted as 4 digits. For example (with the year 20000): `to_date('200001131', 'YYYYMMDD')` will be interpreted as a 4-digit year; instead use a non-digit separator after the year, like `to_date('20000-1131', 'YYYY-MMDD')` or `to_date('20000Nov31', 'YYYYMonDD')`.

- In `to_timestamp` and `to_date`, the `CC` (century) field is accepted but ignored if there is a `YYY`, `YYYY` or `Y,YYY` field. If `CC` is used with `YY` or `Y` then the result is computed as that year in the specified century. If the century is specified but the year is not, the first year of the century is assumed.

- In `to_timestamp` and `to_date`, weekday names or numbers (`DAY`, `D`, and related field types) are accepted but are ignored for purposes of computing the result. The same is true for quarter (`Q`) fields.

- In `to_timestamp` and `to_date`, an ISO 8601 week-numbering date (as distinct from a Gregorian date) can be specified in one of two ways:
  - Year, week number, and weekday: for example `to_date('2006-42-4', 'IYYY-IW-ID')` returns the date 2006-10-19. If you omit the weekday it is assumed to be 1 (Monday).
  - Year and day of year: for example `to_date('2006-291', 'IYYY-IDDD')` also returns 2006-10-19.

Attempting to enter a date using a mixture of ISO 8601 week-numbering fields and Gregorian date fields is nonsensical, and will cause an error. In the context of an ISO 8601 week-numbering year, the concept of a “month” or “day of month” has no meaning. In the context of a Gregorian year, the ISO week has no meaning.

While `to_date` will reject a mixture of Gregorian and ISO week-numbering date fields, `to_char` will not, since output format specifications like `YYYY-MM-DD` (IYYY-IDDD) can be useful. But avoid writing something like `IYYY-MM-DD`; that would yield surprising results near the start of the year. (See Section 9.9.1 for more information.)

- In `to_timestamp`, millisecond (`MS`) or microsecond (`US`) fields are used as the seconds digits after the decimal point. For example `to_timestamp('12.3', 'SS.MS')` is not 3 milliseconds, but 300, because the conversion treats it as 12 + 0.3 seconds. So, for the format `SS.MS`, the input values...
12.3, 12.30, and 12.300 specify the same number of milliseconds. To get three milliseconds, one must write 12.003, which the conversion treats as 12 + 0.003 = 12.003 seconds.

Here is a more complex example: `to_timestamp('15:12:02.020.001230', 'HH24:MI:SS.MS.US')` is 15 hours, 12 minutes, and 2 seconds + 20 milliseconds + 1230 microseconds = 2.021230 seconds.

- `to_char(..., 'ID')`’s day of the week numbering matches the `extract(isodow from ...)` function, but `to_char(..., 'D')`’s does not match `extract(dow from ...)’s day numbering.
- `to_char(interval)` formats HH and HH12 as shown on a 12-hour clock, for example zero hours and 36 hours both output as 12, while HH24 outputs the full hour value, which can exceed 23 in an interval value.

Table 9.28 shows the template patterns available for formatting numeric values.

<table>
<thead>
<tr>
<th>Pattern</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>9</td>

</tr>
<tr>
<td>EEEE</td>
<td>exponent for scientific notation</td>
</tr>
</tbody>
</table>

Usage notes for numeric formatting:
- 0 specifies a digit position that will always be printed, even if it contains a leading/trailing zero. 9 also specifies a digit position, but if it is a leading zero then it will be replaced by a space, while if it is a trailing zero and fill mode is specified then it will be deleted. (For `to_number()`, these two pattern characters are equivalent.)
- The pattern characters S, L, D, and G represent the sign, currency symbol, decimal point, and thousands separator characters defined by the current locale (see `lc_monetary` and `lc_numeric`). The pattern characters period and comma represent those exact characters, with the meanings of decimal point and thousands separator, regardless of locale.
- If no explicit provision is made for a sign in `to_char()`’s pattern, one column will be reserved for the sign, and it will be anchored to (appear just left of) the number. If S appears just left of some 9’s, it will likewise be anchored to the number.
- A sign formatted using SG, PL, or MI is not anchored to the number; for example, `to_char(-12, 'MI9999')` produces ‘- 12’ but `to_char(-12, 'S9999')` produces ’-12’. (The Oracle implementation does not allow the use of MI before 9, but rather requires that 9 precede MI.)
Functions and Operators

- TH does not convert values less than zero and does not convert fractional numbers.
- PL, SG, and TH are Postgres Pro extensions.
- In to_number, if non-data template patterns such as L or TH are used, the corresponding number of input characters are skipped, whether or not they match the template pattern, unless they are data characters (that is, digits, sign, decimal point, or comma). For example, TH would skip two non-data characters.
- V with to_char multiplies the input values by \(10^n\), where \(n\) is the number of digits following V. V with to_number divides in a similar manner. to_char and to_number do not support the use of V combined with a decimal point (e.g., 99.9999 is not allowed).
- EEEE (scientific notation) cannot be used in combination with any of the other formatting patterns or modifiers other than digit and decimal point patterns, and must be at the end of the format string (e.g., 9.999999 is a valid pattern).

Certain modifiers can be applied to any template pattern to alter its behavior. For example, FM99.99 is the 99.99 pattern with the FM modifier. Table 9.29 shows the modifier patterns for numeric formatting.

Table 9.29. Template Pattern Modifiers for Numeric Formatting

### 9.9. Date/Time Functions and Operators

Table 9.32 shows the available functions for date/time value processing, with details appearing in the following subsections. Table 9.31 illustrates the behaviors of the basic arithmetic operators (+, *, etc.). For formatting functions, refer to Section 9.8. You should be familiar with the background information on date/time data types from Section 8.5.

In addition, the usual comparison operators shown in Table 9.1 are available for the date/time types. Dates and timestamps (with or without time zone) are all comparable, while times (with or without time zone) and intervals can only be compared to other values of the same data type. When comparing a timestamp without time zone to a timestamp with time zone, the former value is assumed to be given in the time zone specified by the TimeZone configuration parameter, and is rotated to UTC for comparison to the latter value (which is already in UTC internally). Similarly, a date value is assumed to represent midnight in the TimeZone zone when comparing it to a timestamp.

All the functions and operators described below that take time or timestamp inputs actually come in two variants: one that takes time with time zone or timestamp with time zone, and one that takes time without time zone or timestamp without time zone. For brevity, these variants are not shown separately. Also, the + and * operators come in commutative pairs (for example both date + integer and integer + date); we show only one of each such pair.

</tr>
</tbody>
</table>

---

1. `age()` is defined as a function that subtracts two `timestamp` values and returns an `interval` value. The result is a “symbolic” result that uses years and months, rather than just days.

2. `current_date` and `current_time` functions return the current date and time, respectively, which are subject to change during the execution of a statement. `clock_timestamp()` returns the current date and time along with a time zone indicator, which changes during the course of a statement execution. They are used to obtain the current date and time within a PostgreSQL session.

<td>233</td>
</tr>
</tbody>
</table>
In addition to these functions, the SQL `OVERLAPS` operator is supported:

\[(\text{start1, end1}) \ \text{OVERLAPS} \ (\text{start2, end2})\]

\[(\text{start1, length1}) \ \text{OVERLAPS} \ (\text{start2, length2})\]

This expression yields true when two time periods (defined by their endpoints) overlap, false when they do not overlap. The endpoints can be specified as pairs of dates, times, or time stamps; or as a date, time, or time stamp followed by an interval. When a pair of values is provided, either the start or the end can be written first; (`OVERLAPS`) automatically takes the earlier value of the pair as the start. Each time period is considered to represent the half-open interval `start <= time < end`, unless `start` and `end` are equal in which case it represents that single time instant. This means for instance that two time periods with only an endpoint in common do not overlap.

When adding an interval value to (or subtracting an interval value from) a timestamp with time zone value, the days component advances or decrements the date of the timestamp with time zone by the indicated number of days, keeping the time of day the same. Across daylight saving time changes (when the session time zone is set to a time zone that recognizes DST), this means interval '1 day' does not necessarily equal interval '24 hours'. For example, with the session time zone set to America/Denver:

SELECT timestamp with time zone '2005-04-02 12:00:00-07' + interval '1 day';
Result: 2005-04-03 12:00:00-06

SELECT timestamp with time zone '2005-04-02 12:00:00-07' + interval '24 hours';
Result: 2005-04-03 13:00:00-06

This happens because an hour was skipped due to a change in daylight saving time at 2005-04-03 02:00:00 in time zone America/Denver.

Note there can be ambiguity in the `months` field returned by `age` because different months have different numbers of days. Postgres Pro's approach uses the month from the earlier of the two dates when calculating partial months. For example, `age('2004-06-01', '2004-04-30')` uses April to yield 1 mon 1 day, while using May would yield 1 mon 2 days because May has 31 days, while April has only 30.

Subtraction of dates and timestamps can also be complex. One conceptually simple way to perform subtraction is to convert each value to a number of seconds using `EXTRACT(EPOCH FROM ...)`, then subtract the results; this produces the number of `seconds` between the two values. This will adjust for

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>timeofday()</code></td>
<td>→ Mon Dec 23 14:39:53.662522 2019 EST</td>
<td></td>
</tr>
<tr>
<td><code>transaction_timestamp()</code></td>
<td>→ 2019-12-23 14:39:53.662522-05</td>
<td></td>
</tr>
<tr>
<td><code>to_timestamp(double precision)</code></td>
<td>→ timestamp with time zone</td>
<td></td>
</tr>
<tr>
<td><code>to_timestamp(1284352323)</code></td>
<td>→ 2010-09-13 04:32:03+00</td>
<td></td>
</tr>
</tbody>
</table>
the number of days in each month, timezone changes, and daylight saving time adjustments. Subtraction of date or timestamp values with the “-” operator returns the number of days (24-hours) and hours/minutes/seconds between the values, making the same adjustments. The \texttt{age} function returns years, months, days, and hours/minutes/seconds, performing field-by-field subtraction and then adjusting for negative field values. The following queries illustrate the differences in these approaches. The sample results were produced with \texttt{timezone = 'US/Eastern'}; there is a daylight saving time change between the two dates used:

\begin{verbatim}
SELECT EXTRACT(EPOCH FROM timestamptz '2013-07-01 12:00:00') - 
EXTRACT(EPOCH FROM timestamptz '2013-03-01 12:00:00');
Result: 10537200

SELECT (EXTRACT(EPOCH FROM timestamptz '2013-07-01 12:00:00') - 
EXTRACT(EPOCH FROM timestamptz '2013-03-01 12:00:00'))) 
/ 60 / 60 / 24;
Result: 121.958333333333

SELECT timestamptz '2013-07-01 12:00:00' - timestamptz '2013-03-01 12:00:00';
Result: 121 days 23:00:00

SELECT age(timestamptz '2013-07-01 12:00:00', timestamptz '2013-03-01 12:00:00');
Result: 4 mons
\end{verbatim}

9.9.1. \texttt{EXTRACT, date_part}

\texttt{EXTRACT(field FROM source)}

The \texttt{extract} function retrieves subfields such as year or hour from date/time values. \texttt{source} must be a value expression of type \texttt{timestamp}, \texttt{time}, or \texttt{interval}. (Expressions of type \texttt{date} are cast to \texttt{timestamp} and can therefore be used as well.) \texttt{field} is an identifier or string that selects what field to extract from the source value. The \texttt{extract} function returns values of type \texttt{numeric}. The following are valid field names:

- \texttt{century}
  - The century
    - SELECT \texttt{EXTRACT(CENTURY FROM TIMESTAMP '2000-12-16 12:21:13');}
      \texttt{Result: 20}
    - SELECT \texttt{EXTRACT(CENTURY FROM TIMESTAMP '2001-02-16 20:38:40');}
      \texttt{Result: 21}

    The first century starts at 0001-01-01 00:00:00 AD, although they did not know it at the time. This definition applies to all Gregorian calendar countries. There is no century number 0, you go from -1 century to 1 century. If you disagree with this, please write your complaint to: Pope, Cathedral Saint-Peter of Roma, Vatican.

- \texttt{day}
  - For \texttt{timestamp} values, the day (of the month) field (1-31); for \texttt{interval} values, the number of days
    - SELECT \texttt{EXTRACT(DAY FROM TIMESTAMP '2001-02-16 20:38:40');}
      \texttt{Result: 16}
    - SELECT \texttt{EXTRACT(DAY FROM INTERVAL '40 days 1 minute');}
      \texttt{Result: 40}

- \texttt{decade}
  - The year field divided by 10
    - SELECT \texttt{EXTRACT(DECADE FROM TIMESTAMP '2001-02-16 20:38:40');}
      \texttt{Result: 200}

- \texttt{dow}
  - The day of the week as Sunday (0) to Saturday (6)
SELECT EXTRACT(DOW FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 5

Note that extract's day of the week numbering differs from that of the to_char(..., 'D') function.

doy

The day of the year (1-365/366)

SELECT EXTRACT(DOY FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 47

epoch

For timestamp with time zone values, the number of seconds since 1970-01-01 00:00:00 UTC (negative for timestamps before that); for date and timestamp values, the nominal number of seconds since 1970-01-01 00:00:00, without regard to timezone or daylight-savings rules; for interval values, the total number of seconds in the interval

SELECT EXTRACT(EPOCH FROM TIMESTAMP WITH TIME ZONE '2001-02-16 20:38:40.12-08');
Result: 982384720.12

SELECT EXTRACT(EPOCH FROM TIMESTAMP '2001-02-16 20:38:40.12');
Result: 982355920.12

SELECT EXTRACT(EPOCH FROM INTERVAL '5 days 3 hours');
Result: 442800

You can convert an epoch value back to a timestamp with time zone with to_timestamp:

SELECT to_timestamp(982384720.12);
Result: 2001-02-17 04:38:40.12+00

Beware that applying to_timestamp to an epoch extracted from a date or timestamp value could produce a misleading result: the result will effectively assume that the original value had been given in UTC, which might not be the case.

hour

The hour field (0-23)

SELECT EXTRACT(HOUR FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 20

isodow

The day of the week as Monday (1) to Sunday (7)

SELECT EXTRACT(ISODOW FROM TIMESTAMP '2001-02-18 20:38:40');
Result: 7

This is identical to dow except for Sunday. This matches the ISO 8601 day of the week numbering.

isoyear

The ISO 8601 week-numbering year that the date falls in (not applicable to intervals)

SELECT EXTRACT(ISOYEAR FROM DATE '2006-01-01');
Result: 2005
SELECT EXTRACT(ISOYEAR FROM DATE '2006-01-02');
Result: 2006

Each ISO 8601 week-numbering year begins with the Monday of the week containing the 4th of January, so in early January or late December the ISO year may be different from the Gregorian year. See the week field for more information.
This field is not available in PostgreSQL releases prior to 8.3.

### julian

The *Julian Date* corresponding to the date or timestamp (not applicable to intervals). Timestamps that are not local midnight result in a fractional value. See Section B.7 for more information.

```sql
SELECT EXTRACT(JULIAN FROM DATE '2006-01-01');
Result: 2453737
```

```sql
SELECT EXTRACT(JULIAN FROM TIMESTAMP '2006-01-01 12:00');
Result: 2453737.50000000000000000000
```

### microseconds

The seconds field, including fractional parts, multiplied by 1 000 000; note that this includes full seconds.

```sql
SELECT EXTRACT(MICROSECONDS FROM TIME '17:12:28.5');
Result: 28500000
```

### millennium

The millennium

```sql
SELECT EXTRACT(MILLENNIUM FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 3
```

Years in the 1900s are in the second millennium. The third millennium started January 1, 2001.

### milliseconds

The seconds field, including fractional parts, multiplied by 1000. Note that this includes full seconds.

```sql
SELECT EXTRACT(MILLISECONDS FROM TIME '17:12:28.5');
Result: 28500
```

### minute

The minutes field (0–59)

```sql
SELECT EXTRACT(MINUTE FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 38
```

### month

For *timestamp* values, the number of the month within the year (1–12); for *interval* values, the number of months, modulo 12 (0–11)

```sql
SELECT EXTRACT(MONTH FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 2
```

```sql
SELECT EXTRACT(MONTH FROM INTERVAL '2 years 3 months');
Result: 3
```

```sql
SELECT EXTRACT(MONTH FROM INTERVAL '2 years 13 months');
Result: 1
```

### quarter

The quarter of the year (1–4) that the date is in

```sql
SELECT EXTRACT(QUARTER FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 1
```

### second

The seconds field, including any fractional seconds
SELECT EXTRACT(SECOND FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 40

SELECT EXTRACT(SECOND FROM TIME '17:12:28.5');
Result: 28.5

timezone

The time zone offset from UTC, measured in seconds. Positive values correspond to time zones east of UTC, negative values to zones west of UTC. (Technically, Postgres Pro does not use UTC because leap seconds are not handled.)

timezone_hour

The hour component of the time zone offset

timezone_minute

The minute component of the time zone offset

week

The number of the ISO 8601 week-numbering week of the year. By definition, ISO weeks start on Mondays and the first week of a year contains January 4 of that year. In other words, the first Thursday of a year is in week 1 of that year.

In the ISO week-numbering system, it is possible for early-January dates to be part of the 52nd or 53rd week of the previous year, and for late-December dates to be part of the first week of the next year. For example, 2005-01-01 is part of the 53rd week of year 2004, and 2006-01-01 is part of the 52nd week of year 2005, while 2012-12-31 is part of the first week of 2013. It's recommended to use the isoyear field together with week to get consistent results.

SELECT EXTRACT(WEEK FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 7

year

The year field. Keep in mind there is no 0 AD, so subtracting BC years from AD years should be done with care.

SELECT EXTRACT(YEAR FROM TIMESTAMP '2001-02-16 20:38:40');
Result: 2001

Note

When the input value is +/-Infinity, extract returns +/-Infinity for monotonically-increasing fields (epoch, julian, year, isoyear, decade, century, and millennium). For other fields, NULL is returned. Postgres Pro versions before 9.6 returned zero for all cases of infinite input.

The extract function is primarily intended for computational processing. For formatting date/time values for display, see Section 9.8.

The date_part function is modeled on the traditional Ingres equivalent to the SQL-standard function extract:

date_part('field', source)

Note that here the field parameter needs to be a string value, not a name. The valid field names for date_part are the same as for extract. For historical reasons, the date_part function returns values of type double precision. This can result in a loss of precision in certain uses. Using extract is recommended instead.
9.9.2. date_trunc

The function `date_trunc` is conceptually similar to the `trunc` function for numbers.

`date_trunc(field, source [, time_zone ])`

`source` is a value expression of type `timestamp`, `timestamp with time zone`, or `interval`. (Values of type `date` and `time` are cast automatically to `timestamp` or `interval`, respectively.) `field` selects to which precision to truncate the input value. The return value is likewise of type `timestamp`, `timestamp with time zone`, or `interval`, and it has all fields that are less significant than the selected one set to zero (or one, for day and month).

Valid values for `field` are:

- microseconds
- milliseconds
- second
- minute
- hour
- day
- week
- month
- quarter
- year
- decade
- century
- millennium

When the input value is of type `timestamp with time zone`, the truncation is performed with respect to a particular time zone; for example, truncation to `day` produces a value that is midnight in that zone. By default, truncation is done with respect to the current `TimeZone` setting, but the optional `time_zone` argument can be provided to specify a different time zone. The time zone name can be specified in any of the ways described in Section 8.5.3.

A time zone cannot be specified when processing `timestamp without time zone` or `interval` inputs. These are always taken at face value.

Examples (assuming the local time zone is `America/New_York`):

- `SELECT date_trunc('hour', TIMESTAMP '2001-02-16 20:38:40');`
  `Result: 2001-02-16 20:00:00`

- `SELECT date_trunc('year', TIMESTAMP '2001-02-16 20:38:40');`
  `Result: 2001-01-01 00:00:00`

- `SELECT date_trunc('day', TIMESTAMP WITH TIME ZONE '2001-02-16 20:38:40+00');`
  `Result: 2001-02-16 00:00:00-05`

- `SELECT date_trunc('day', TIMESTAMP WITH TIME ZONE '2001-02-16 20:38:40+00', 'Australia/Sydney');`
  `Result: 2001-02-16 08:00:00-05`

- `SELECT date_trunc('hour', INTERVAL '4 hours 3 minutes');`

```sql
SELECT date_part('day', TIMESTAMP '2001-02-16 20:38:40');
Result: 16

SELECT date_part('hour', INTERVAL '4 hours 3 minutes');
Result: 4
```
### 9.9.3. date_bin

The function `date_bin` "bins" the input timestamp into the specified interval (the `stride`) aligned with a specified origin.

\[
date_bin(stride, source, origin)
\]

`source` is a value expression of type `timestamp` or `timestamp with time zone`. (Values of type `date` are cast automatically to `timestamp`.) `stride` is a value expression of type `interval`. The return value is likewise of type `timestamp` or `timestamp with time zone`, and it marks the beginning of the bin into which the `source` is placed.

**Examples:**

- `SELECT date_bin('15 minutes', TIMESTAMP '2020-02-11 15:44:17', TIMESTAMP '2001-01-01');`
  - **Result:** `2020-02-11 15:30:00`

- `SELECT date_bin('15 minutes', TIMESTAMP '2020-02-11 15:44:17', TIMESTAMP '2001-01-01 00:02:30');`
  - **Result:** `2020-02-11 15:32:30`

In the case of full units (1 minute, 1 hour, etc.), it gives the same result as the analogous `date_trunc` call, but the difference is that `date_bin` can truncate to an arbitrary interval.

The `stride` interval must be greater than zero and cannot contain units of month or larger.

### 9.9.4. AT TIME ZONE

The `AT TIME ZONE` operator converts time stamp without time zone to/from time stamp with time zone, and time with time zone values to different time zones. Table 9.33 shows its variants.

**Table 9.33. AT TIME ZONE Variants**

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>timestamp without time zone <code>AT TIME ZONE zone</code> → timestamp with time zone</td>
<td>Converts given time stamp without time zone to time stamp with time zone, assuming the given value is in the named time zone.</td>
<td>timestamp '2001-02-16 20:38:40' at time zone 'America/Denver' → 2001-02-16 03:38:40+00</td>
</tr>
</tbody>
</table>

| timestamp with time zone `AT TIME ZONE zone` → timestamp without time zone | Converts given time stamp with time zone to time stamp without time zone, as the time would appear in that zone. | timestamp with time zone '2001-02-16 20:38:40-05' at time zone 'America/Denver' → 2001-02-16 18:38:40 |

| time with time zone `AT TIME ZONE zone` → time with time zone | Converts given time with time zone to a new time zone. Since no date is supplied, this uses the currently active UTC offset for the named destination zone. | time with time zone '05:34:17-05' at time zone 'UTC' → 10:34:17+00 |

In these expressions, the desired time zone `zone` can be specified either as a text value (e.g., 'America/Los_Angeles') or as an interval (e.g., `INTERVAL '-08:00'`). In the text case, a time zone name can be specified in any of the ways described in Section 8.5.3. The interval case is only useful for zones that have fixed offsets from UTC, so it is not very common in practice.
Examples (assuming the current TimeZone setting is America/Los_Angeles):

SELECT TIMESTAMP '2001-02-16 20:38:40' AT TIME ZONE 'America/Denver';
Result: 2001-02-16 19:38:40-08

SELECT TIMESTAMP WITH TIME ZONE '2001-02-16 20:38:40-05' AT TIME ZONE 'America/Denver';
Result: 2001-02-16 18:38:40

SELECT TIMESTAMP '2001-02-16 20:38:40' AT TIME ZONE 'Asia/Tokyo' AT TIME ZONE 'America/Chicago';
Result: 2001-02-16 05:38:40

The first example adds a time zone to a value that lacks it, and displays the value using the current TimeZone setting. The second example shifts the time stamp with time zone value to the specified time zone, and returns the value without a time zone. This allows storage and display of values different from the current TimeZone setting. The third example converts Tokyo time to Chicago time.

The function timezone(zone, timestamp) is equivalent to the SQL-conforming construct timestamp AT TIME ZONE zone.

9.9.5. Current Date/Time

Postgres Pro provides a number of functions that return values related to the current date and time. These SQL-standard functions all return values based on the start time of the current transaction:

CURRENT_DATE
CURRENT_TIME
CURRENT_TIMESTAMP
CURRENT_TIME(precision)
CURRENT_TIMESTAMP(precision)
LOCALTIME
LOCTIMESTAMP
LOCTIME(precision)
LOCTIMESTAMP(precision)

CURRENT_TIME and CURRENT_TIMESTAMP deliver values with time zone; LOCALTIME and LOCTIMESTAMP deliver values without time zone.

CURRENT_TIME, CURRENT_TIMESTAMP, LOCALTIME, and LOCTIMESTAMP can optionally take a precision parameter, which causes the result to be rounded to that many fractional digits in the seconds field. Without a precision parameter, the result is given to the full available precision.

Some examples:

SELECT CURRENT_TIME;
Result: 14:39:53.662522-05

SELECT CURRENT_DATE;
Result: 2019-12-23

SELECT CURRENT_TIMESTAMP;
Result: 2019-12-23 14:39:53.662522-05

SELECT CURRENT_TIMESTAMP(2);
Result: 2019-12-23 14:39:53.66-05

SELECT LOCTIMESTAMP;
Result: 2019-12-23 14:39:53.662522

Since these functions return the start time of the current transaction, their values do not change during the transaction. This is considered a feature: the intent is to allow a single transaction to have a consistent
notion of the “current” time, so that multiple modifications within the same transaction bear the same time stamp.

**Note**
Other database systems might advance these values more frequently.

Postgres Pro also provides functions that return the start time of the current statement, as well as the actual current time at the instant the function is called. The complete list of non-SQL-standard time functions is:

- `transaction_timestamp()`
- `statement_timestamp()`
- `clock_timestamp()`
- `timeofday()`
- `now()`

`transaction_timestamp()` is equivalent to `CURRENT_TIMESTAMP`, but is named to clearly reflect what it returns. `statement_timestamp()` returns the start time of the current statement (more specifically, the time of receipt of the latest command message from the client). `statement_timestamp()` and `transaction_timestamp()` return the same value during the first command of a transaction, but might differ during subsequent commands. `clock_timestamp()` returns the actual current time, and therefore its value changes even within a single SQL command. `timeofday()` is a historical Postgres Pro function. Like `clock_timestamp()`, it returns the actual current time, but as a formatted text string rather than a `timestamp` with time zone value. `now()` is a traditional Postgres Pro equivalent to `transaction_timestamp()`.

All the date/time data types also accept the special literal value `now` to specify the current date and time (again, interpreted as the transaction start time). Thus, the following three all return the same result:

```sql
SELECT CURRENT_TIMESTAMP;
SELECT now();
SELECT TIMESTAMP 'now'; -- but see tip below
```

**Tip**
Do not use the third form when specifying a value to be evaluated later, for example in a `DEFAULT` clause for a table column. The system will convert `now` to a `timestamp` as soon as the constant is parsed, so that when the default value is needed, the time of the table creation would be used! The first two forms will not be evaluated until the default value is used, because they are function calls. Thus they will give the desired behavior of defaulting to the time of row insertion. (See also Section 8.5.1.4.)

### 9.9.6. Delaying Execution

The following functions are available to delay execution of the server process:

- `pg_sleep ( double precision )`
- `pg_sleep_for ( interval )`
- `pg_sleep_until ( timestamp with time zone )`

`pg_sleep` makes the current session's process sleep until the given number of seconds have elapsed. Fractional-second delays can be specified. `pg_sleep_for` is a convenience function to allow the sleep time to be specified as an `interval`. `pg_sleep_until` is a convenience function for when a specific wake-up time is desired. For example:

```sql
SELECT pg_sleep(1.5);
SELECT pg_sleep_for('5 minutes');
SELECT pg_sleep_until('tomorrow 03:00');
```
Note
The effective resolution of the sleep interval is platform-specific; 0.01 seconds is a common value. The sleep delay will be at least as long as specified. It might be longer depending on factors such as server load. In particular, `pg_sleep_until` is not guaranteed to wake up exactly at the specified time, but it will not wake up any earlier.

Warning
Make sure that your session does not hold more locks than necessary when calling `pg_sleep` or its variants. Otherwise other sessions might have to wait for your sleeping process, slowing down the entire system.

9.10. Enum Support Functions
For enum types (described in Section 8.7), there are several functions that allow cleaner programming without hard-coding particular values of an enum type. These are listed in Table 9.34. The examples assume an enum type created as:

```
CREATE TYPE rainbow AS ENUM ('red', 'orange', 'yellow', 'green', 'blue', 'purple');
```

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>enum_first()</code></td>
<td>Returns the first value of the input enum type.</td>
<td><code>enum_first(null::rainbow)</code> → <code>red</code></td>
</tr>
<tr>
<td><code>enum_last()</code></td>
<td>Returns the last value of the input enum type.</td>
<td><code>enum_last(null::rainbow)</code> → <code>purple</code></td>
</tr>
<tr>
<td><code>enum_range()</code></td>
<td>Returns all values of the input enum type in an ordered array.</td>
<td><code>enum_range(null::rainbow)</code> → <code>{red, orange, yellow, green, blue, purple}</code></td>
</tr>
</tbody>
</table>
| `enum_range()`| Returns the range between the two given enum values, as an ordered array. The values must be from the same enum type. If the first parameter is null, the result will start with the first value of the enum type. If the second parameter is null, the result will end with the last value of the enum type. | `enum_range('orange'::rainbow, 'green'::rainbow)` → `{orange, yellow, green}`  
|               |                                                  | `enum_range(NULL, 'green'::rainbow)` → `{red, orange, yellow, green}`       |
|               |                                                  | `enum_range('orange'::rainbow, NULL)` → `{orange, yellow, green, blue, purple}` |

Notice that except for the two-argument form of `enum_range`, these functions disregard the specific value passed to them; they care only about its declared data type. Either null or a specific value of the type can be passed, with the same result. It is more common to apply these functions to a table column or function argument than to a hardwired type name as used in the examples.

9.11. Geometric Functions and Operators
The geometric types `point`, `box`, `lseg`, `line`, `path`, `polygon`, and `circle` have a large set of native support functions and operators, shown in Table 9.35, Table 9.36, and Table 9.37.
### Table 9.35. Geometric Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>geometric_type + point → geometric_type</td>
<td>Adds the coordinates of the second point to those of each point of the first argument, thus performing translation. Available for point, box, path, circle.</td>
<td>box '((1,1),(0,0))' + point '((2,0))' → (3,1),(2,0)</td>
</tr>
<tr>
<td>path + path → path</td>
<td>Concatenates two open paths (returns NULL if either path is closed).</td>
<td>path '[(0,0),(1,1)]' + path '[(2,2),(3,3),(4,4)]' → [(0,0),(1,1),(2,2),(3,3),(4,4)]</td>
</tr>
<tr>
<td>geometric_type - point → geometric_type</td>
<td>Subtracts the coordinates of the second point from those of each point of the first argument, thus performing translation. Available for point, box, path, circle.</td>
<td>box '((1,1),(0,0))' - point '((2,0))' → (-1,1),(-2,0)</td>
</tr>
<tr>
<td>geometric_type * point → geometric_type</td>
<td>Multiplies each point of the first argument by the second point (treating a point as being a complex number represented by real and imaginary parts, and performing standard complex multiplication). If one interprets the second point as a vector, this is equivalent to scaling the object's size and distance from the origin by the length of the vector, and rotating it counterclockwise around the origin by the vector's angle from the x axis. Available for point, box, path, circle.</td>
<td>path '[(0,0),(1,0),(1,1)]' * point '((3.0,0))' → ((0,0),(3,0),(3,3)),(0.7071067811865476,-0.7071067811865476),(1.4142135623730951,0))</td>
</tr>
<tr>
<td>geometric_type / point → geometric_type</td>
<td>Divides each point of the first argument by the second point (treating a point as being a complex number represented by real and imaginary parts, and performing standard complex division). If one interprets the second point as a vector, this is equivalent to scaling the object's size and distance from the origin down by the length of the vector, and rotating it clockwise around the origin by the vector's angle from the x axis. Available for point, box, path, circle.</td>
<td>path '[(0,0),(1,0),(1,1)]' / point '((2.0,0))' → ((0,0),(0.5,0),(0.5,0.5)),(0.7071067811865476,-0.7071067811865476),(1.4142135623730951,0))</td>
</tr>
<tr>
<td>@-@ geometric_type → double precision</td>
<td>Computes the total length. Available for lseg, path.</td>
<td>@-@ path '[(0,0),(1,1),(1,1)]' → 2</td>
</tr>
<tr>
<td>@@ geometric_type → point</td>
<td>Computes the center point. Available for box, lseg, path, polygon, circle.</td>
<td>@@ box '((2,2),(0,0))' → (1,1)</td>
</tr>
<tr>
<td># geometric_type → integer</td>
<td>Returns the number of points. Available for path, polygon.</td>
<td># path '[(1,0),(0,1),(-1,0)]' → 3</td>
</tr>
<tr>
<td>Operator</td>
<td>Description</td>
<td>Example(s)</td>
</tr>
<tr>
<td>-------------------------------</td>
<td>-----------------------------------------------------------------------------</td>
<td>-----------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td><code>lseg [(0,0),(1,1)]</code> # <code>lseg [(1,0),(0,1)]</code></td>
<td>Computes the point of intersection, or NULL if there is none. Available for <code>lseg</code>, <code>line</code>.</td>
<td><code>(0.5,0.5)</code></td>
</tr>
<tr>
<td><code>box (2,2),(-1,-1)</code> # <code>box (1,1),(-2,-2)</code></td>
<td>Computes the intersection of two boxes, or NULL if there is none.</td>
<td><code>(1,1),(-1,-1)</code></td>
</tr>
<tr>
<td><code>point '(0,0)' # lseg '((2,0),(0,2)]'</code></td>
<td>Computes the closest point to the first object on the second object. Available for these pairs of types: (<code>point</code>, <code>box</code>), (<code>point</code>, <code>lseg</code>), (<code>point</code>, <code>line</code>), (<code>lseg</code>, <code>box</code>), (<code>lseg</code>, <code>lseg</code>), (<code>lseg</code>, <code>line</code>), (<code>line</code>, <code>box</code>), (<code>line</code>, <code>lseg</code>).</td>
<td><em>(Result not shown)</em></td>
</tr>
<tr>
<td><code>circle '&lt;(0,0),1&gt;' &lt;-&gt; circle '&lt;(5,0),1&gt;'</code></td>
<td>Computes the distance between the objects. Available for all seven geometric types, for all combinations of <code>point</code> with another geometric type, and for these additional pairs of types: (<code>box</code>, <code>lseg</code>), (<code>box</code>, <code>line</code>), (<code>lseg</code>, <code>line</code>), (<code>polygon</code>, <code>circle</code>) (and the commutator cases).</td>
<td><code>3</code></td>
</tr>
<tr>
<td><code>point '(1,1)' &lt;@ circle '&lt;(0,0),2&gt;'</code></td>
<td>Computes the closest point to the first object on the second object. Available for these pairs of types: (<code>point</code>, <code>box</code>), (<code>point</code>, <code>lseg</code>), (<code>point</code>, <code>line</code>), (<code>point</code>, <code>path</code>), (<code>point</code>, <code>polygon</code>), (<code>point</code>, <code>circle</code>), (<code>box</code>, <code>box</code>), (<code>lseg</code>, <code>box</code>), (<code>lseg</code>, <code>line</code>), (<code>polygon</code>, <code>polygon</code>), (<code>circle</code>, <code>circle</code>).</td>
<td><em>(Result not shown)</em></td>
</tr>
<tr>
<td><code>box '(1,1),(0,0)' &amp;&lt; box '(2,2),(0,0)'</code></td>

### Functions and Operators

#### Operator

<table>
<thead>
<tr>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Are these objects the same? Available for <strong>point</strong>, <strong>box</strong>, <strong>polygon</strong>, <strong>circle</strong>.</td>
<td><code>polygon '((0,0),(1,1))' ~= polygon '((1,1),(0,0))' → t</code></td>
</tr>
</tbody>
</table>

*“Rotating” a box with these operators only moves its corner points; the box is still considered to have sides parallel to the axes. Hence the box’s size is not preserved, as a true rotation would do.*

#### Caution

Note that the “same as” operator, `~=` represents the usual notion of equality for the **point**, **box**, **polygon**, and **circle** types. Some of the geometric types also have an `=` operator, but `=` compares for equal **areas** only. The other scalar comparison operators (`<`, `<=` and so on), where available for these types, likewise compare areas.

#### Note

Before PostgreSQL 14, the point is strictly below/above comparison operators `point <<| point` and `point |>> point` were respectively called `<<` and `>>`. These names are still available, but are deprecated and will eventually be removed.

#### Table 9.36. Geometric Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>area(geometric_type) → double precision</code></td>
<td>Computes area. Available for <strong>box</strong>, <strong>path</strong>, <strong>circle</strong>. A path input must be closed, else NULL is returned. Also, if the path is self-intersecting, the result may be meaningless.</td>
<td><code>area(box '(2,2),(0,0)') → 4</code></td>
</tr>
<tr>
<td><code>center(geometric_type) → point</code></td>
<td>Computes center point. Available for <strong>box</strong>, <strong>circle</strong>.</td>
<td><code>center(box '(1,2),(0,0)') → (0.5,1)</code></td>
</tr>
<tr>
<td><code>diagonal(box) → lseg</code></td>
<td>Extracts box’s diagonal as a line segment (same as <code>lseg(box)</code>).</td>
<td><code>diagonal(box '(1,2),(0,0)') → [(1,2),(0,0)]</code></td>
</tr>
<tr>
<td><code>diameter(circle) → double precision</code></td>
<td>Computes diameter of circle.</td>
<td><code>diameter(circle '&lt;(0,0),2&gt;') → 4</code></td>
</tr>
<tr>
<td><code>height(box) → double precision</code></td>
<td>Computes vertical size of box.</td>
<td><code>height(box '(1,2),(0,0)') → 2</code></td>
</tr>
<tr>
<td><code>isclosed(path) → boolean</code></td>
<td>Is path closed?</td>
<td><code>isclosed(path '(((0,0),(1,1),(2,0)))' → t</code></td>
</tr>
<tr>
<td><code>isopen(path) → boolean</code></td>
<td>Is path open?</td>
<td><code>isopen(path '[(0,0),(1,1),(2,0)]') → t</code></td>
</tr>
<tr>
<td><code>length(geometric_type) → double precision</code></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
### Function

<table>
<thead>
<tr>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Computes the total length. Available for <code>lseg</code>, <code>path</code>.</td>
<td><code>length(path '((-1,0),(1,0))') → 4</code></td>
</tr>
</tbody>
</table>

**npoints** (`geometric_type`) → integer

Returns the number of points. Available for `path`, `polygon`.

**npoints**(`path '[(0,0),(1,1),(2,0)]') → 3

**pclose** (`path`) → `path`

Converts path to closed form.

**pclose**(`path '[(0,0),(1,1),(2,0)]') → `((0,0),(1,1),(2,0))`

**popen** (`path`) → `path`

Converts path to open form.

**popen**(`path '((0,0),(1,1),(2,0))') → `[(0,0),(1,1),(2,0)]`

**radius** (`circle`) → `double precision`

Computes radius of circle.

**radius**(`circle '<(0,0),2>'`) → 2

**slope** (`point`, `point`) → `double precision`

Computes slope of a line drawn through the two points.

**slope**(`point '(0,0)', point '(2,1)') → 0.5

**width** (`box`) → `double precision`

Computes horizontal size of box.

**width**(`box '(1,2),(0,0)') → 1

### Table 9.37. Geometric Type Conversion Functions

<table>

</thead>
<tbody>
<tr>
<td><code>circle(box '(1,1),(0,0)')</code></td>
<td>${\rightarrow}&lt;0.5,0.5&gt;,0.7071067811865476&gt;</td>
<td></td>
</tr>
<tr>
<td><code>circle(point, double precision) → circle</code></td>
<td>Constructs circle from center and radius.</td>
<td><code>circle(point '(0,0)', 2.0) →&lt;0,0,2&gt;</code></td>
</tr>
<tr>
<td><code>circle(polygon) → circle</code></td>
<td>Converts polygon to circle. The circle's center is the mean of the positions of the polygon's points, and the radius is the average distance of the polygon's points from that center.</td>
<td><code>circle(polygon '((0,0),(1,3),(2,0))') →&lt;1,1,1.6094757082487299&gt;</code></td>
</tr>
<tr>
<td><code>line(point, point) → line</code></td>
<td>Converts two points to the line through them.</td>
<td><code>line(point '(-1,0)', point '(1,0)') → {-1,0,0}</code></td>
</tr>
<tr>
<td><code>lseg(box) → lseg</code></td>
<td>Extracts box's diagonal as a line segment.</td>
<td><code>lseg(box '(-1,0),(-1,0)') → [-1,0,-1,0]</code></td>
</tr>
<tr>
<td><code>lseg(point, point) → lseg</code></td>
<td>Constructs line segment from two endpoints.</td>
<td><code>lseg(point '(-1,0)', point '(1,0)') → [-1,0,1,0]</code></td>
</tr>
<tr>
<td><code>path(polygon) → path</code></td>
<td>Converts polygon to a closed path with the same list of points.</td>
<td><code>path(polygon '((0,0),(1,1),(2,0))') → ((0,0),(1,1),(2,0))</code></td>
</tr>
<tr>
<td><code>point(double precision, double precision) → point</code></td>
<td>Constructs point from its coordinates.</td>
<td><code>point(23.4, -44.5) → (23.4,-44.5)</code></td>
</tr>
<tr>
<td><code>point(box) → point</code></td>
<td>Computes center of box.</td>
<td><code>point(box '(1,0),(-1,0)') → (0,0)</code></td>
</tr>
<tr>
<td><code>point(circle) → point</code></td>
<td>Computes center of circle.</td>
<td><code>point(circle '&lt;(0,0),2&gt;') → (0,0)</code></td>
</tr>
<tr>
<td><code>point(lseg) → point</code></td>
<td>Computes center of line segment.</td>
<td><code>point(lseg '(-1,0),(1,0)') → (0,0)</code></td>
</tr>
<tr>
<td><code>point(polygon) → point</code></td>
<td>Computes center of polygon (the mean of the positions of the polygon's points).</td>
<td><code>point(polygon '((0,0),(1,1),(2,0))') → (1,0.3333333333333333)</code></td>
</tr>
<tr>
<td><code>polygon(box) → polygon</code></td>
<td>Converts box to a 4-point polygon.</td>
<td><code>polygon(box '(1,0),(0,0)') → ((0,0),(0,1),(1,1),(1,0))</code></td>
</tr>
<tr>
<td><code>polygon(circle) → polygon</code></td>
<td>Converts circle to a 12-point polygon.</td>
<td><code>polygon(circle '&lt;(0,0),2&gt;') → ((-2,0),(-1.7320508075688774,0.9999999999999999),(-1.0000000000000002,1.7320508075688772),(</code></td>
</tr>
</tbody>
</table>
### Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>polygon(integer, circle) → polygon</td>
<td>Converts circle to an n-point polygon.</td>
<td>polygon(4, circle '&lt;(3,0),1&gt;') → ((2,0),(3,1),(4,1.2246063538223773e-16),(3,-1))</td>
</tr>
<tr>
<td>polygon(path) → polygon</td>
<td>Converts closed path to a polygon with the same list of points.</td>
<td>polygon(path '((0,0),(1,1),(2,0))') → ((0,0),(1,1),(2,0))</td>
</tr>
</tbody>
</table>

It is possible to access the two component numbers of a point as though the point were an array with indexes 0 and 1. For example, if \( t.p \) is a point column then `SELECT p[0] FROM t` retrieves the X coordinate and `UPDATE t SET p[1] = ...` changes the Y coordinate. In the same way, a value of type `box` or `lseg` can be treated as an array of two point values.

### 9.12. Network Address Functions and Operators

The IP network address types, `cidr` and `inet`, support the usual comparison operators shown in Table 9.1 as well as the specialized operators and functions shown in Table 9.38 and Table 9.39.

Any `cidr` value can be cast to `inet` implicitly; therefore, the operators and functions shown below as operating on `inet` also work on `cidr` values. (Where there are separate functions for `inet` and `cidr`, it is because the behavior should be different for the two cases.) Also, it is permitted to cast an `inet` value to `cidr`. When this is done, any bits to the right of the netmask are silently zeroed to create a valid `cidr` value.

#### Table 9.38. IP Address Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \text{inet} \ll \text{inet} \rightarrow \text{boolean} )</td>
<td>Is subnet strictly contained by subnet? This operator, and the next four, test for subnet inclusion. They consider only the network parts of the two addresses (ignoring any bits to the right of the netmasks) and determine whether one network is identical to or a subnet of the other.</td>
<td>( \text{inet '192.168.1.5'} \ll \text{inet '192.168.1/24'} \rightarrow \text{t} )</td>
</tr>
<tr>
<td>( \text{inet} \ll= \text{inet} \rightarrow \text{boolean} )</td>
<td>Is subnet contained by or equal to subnet?</td>
<td>( \text{inet '192.168.1/24'} \ll= \text{inet '192.168.1/24'} \rightarrow \text{t} )</td>
</tr>
<tr>
<td>( \text{inet} \gg \text{inet} \rightarrow \text{boolean} )</td>
<td>Does subnet strictly contain subnet?</td>
<td>( \text{inet '192.168.1/24'} \gg \text{inet '192.168.1.5'} \rightarrow \text{t} )</td>
</tr>
<tr>
<td>( \text{inet} \gg= \text{inet} \rightarrow \text{boolean} )</td>
<td></td>
<td></td>

</tr>
<tr>
<td><code>set_masklen(cidr '192.168.1.0/24', 16)</code></td>
<td>Sets the netmask length for a <code>cidr</code> value. Address bits to the right of the new netmask are set to zero.</td>
<td><code>→ 192.168.0.0/16</code></td>
</tr>
<tr>
<td><code>text(inet '192.168.1.5')</code></td>
<td>Returns the unabbreviated IP address and netmask length as text. (This has the same result as an explicit cast to <code>text</code>.)</td>
<td><code>→ 192.168.1.5/32</code></td>
</tr>
</tbody>
</table>

### Tip

The `abbrev`, `host`, and `text` functions are primarily intended to offer alternative display formats for IP addresses.
The MAC address types, `macaddr` and `macaddr8`, support the usual comparison operators shown in Table 9.1 as well as the specialized functions shown in Table 9.40. In addition, they support the bitwise logical operators ~, & and | (NOT, AND and OR), just as shown above for IP addresses.

### Table 9.40. MAC Address Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>trunc(macaddr)</code> → <code>macaddr</code></td>
<td>Sets the last 3 bytes of the address to zero. The remaining prefix can be associated with a particular manufacturer (using data not included in PostgreSQL).</td>
<td><code>trunc(macaddr '12:34:56:78:90:ab')</code> → <code>12:34:56:00:00:00</code></td>
</tr>
<tr>
<td><code>trunc(macaddr8)</code> → <code>macaddr8</code></td>
<td>Sets the last 5 bytes of the address to zero. The remaining prefix can be associated with a particular manufacturer (using data not included in PostgreSQL).</td>
<td><code>trunc(macaddr8 '12:34:56:78:90:ab:cd:ef')</code> → <code>12:34:56:00:00:00:00:00</code></td>
</tr>
<tr>
<td><code>macaddr8_set7bit(macaddr8)</code> → <code>macaddr8</code></td>
<td>Sets the 7th bit of the address to one, creating what is known as modified EUI-64, for inclusion in an IPv6 address.</td>
<td><code>macaddr8_set7bit(macaddr8 '00:34:56:ab:cd:ef')</code> → <code>02:34:56:ff:fe:ab:cd:ef</code></td>
</tr>
</tbody>
</table>

### 9.13. Text Search Functions and Operators

Table 9.41, Table 9.42 and Table 9.43 summarize the functions and operators that are provided for full text searching. See Chapter 12 for a detailed explanation of Postgres Pro's text search facility.

### Table 9.41. Text Search Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>tsvector @@ tsquery</code> → <code>boolean</code></td>
<td>Does <code>tsvector</code> match <code>tsquery</code>? (The arguments can be given in either order.)</td>
<td><code>to_tsvector('fat cats ate rats') @@ to_tsquery('cat &amp; rat')</code> → <code>t</code></td>
</tr>
<tr>
<td><code>tsquery @@ tsvector</code> → <code>boolean</code></td>
<td>Does text string, after implicit invocation of <code>to_tsvector()</code>, match <code>tsquery</code>?</td>
<td><code>to_tsvector('fat cats ate rats') @@ to_tsquery('cat &amp; rat')</code> → <code>t</code></td>
</tr>
<tr>
<td><code>text @@ tsquery</code> → <code>boolean</code></td>
<td>This is a deprecated synonym for <code>@</code>.</td>
<td><code>to_tsvector('fat cats ate rats') @@ to_tsquery('cat &amp; rat')</code> → <code>t</code></td>
</tr>
<tr>
<td>`tsvector</td>
<td></td>
<td>tsquery<code>→</code>tsvector`</td>
</tr>
<tr>
<td><code>tsquery &amp;&amp; tsquery</code> → <code>tsquery</code></td>
<td>ANDs two <code>tsqueries</code> together, producing a query that matches documents that match both input queries.</td>
<td>`'fat</td>
</tr>
</tbody>
</table>
### Functions and Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>tsquery</td>
<td></td>
<td>tsquery → tsquery</td>
</tr>
<tr>
<td>!! tsquery → tsquery</td>
<td>Negates a tsquery, producing a query that matches documents that do not match the input query.</td>
<td>!! 'cat':tsquery → !'cat'</td>
</tr>
<tr>
<td>tsquery &lt;-&gt; tsquery</td>
<td>Constructs a phrase query, which matches if the two input queries match at successive lexemes.</td>
<td>to_tsquery('fat') &lt;-&gt; to_tsquery('rat') → 'fat' &lt;-&gt; 'rat'</td>
</tr>
<tr>
<td>tsquery @&gt; tsquery → boolean</td>
<td>Does first tsquery contain the second? (This considers only whether all the lexemes appearing in one query appear in the other, ignoring the combining operators.)</td>
<td>'cat':tsquery @&gt; 'cat &amp; rat':tsquery → f</td>
</tr>
<tr>
<td>tsquery &lt;@ tsquery → boolean</td>
<td>Is first tsquery contained in the second? (This considers only whether all the lexemes appearing in one query appear in the other, ignoring the combining operators.)</td>
<td>'cat':tsquery &lt;@ 'cat &amp; rat':tsquery → t</td>
</tr>
<tr>
<td></td>
<td></td>
<td>'cat':tsquery &lt;@ '!cat &amp; rat':tsquery → t</td>
</tr>
</tbody>
</table>

In addition to these specialized operators, the usual comparison operators shown in Table 9.1 are available for types tsvector and tsquery. These are not very useful for text searching but allow, for example, unique indexes to be built on columns of these types.

### Table 9.42. Text Search Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>array_to_tsvector</td>
<td>Converts an array of lexemes to a tsvector. The given strings are used as-is without further processing.</td>
<td>array_to_tsvector('{fat,cat,rat}'::text[]) → 'cat' 'fat' 'rat'</td>
</tr>
<tr>
<td>get_current_ts_config</td>
<td>Returns the OID of the current default text search configuration (as set by default_text_search_config).</td>
<td>get_current_ts_config() → english</td>
</tr>
<tr>
<td>length</td>
<td>Returns the number of lexemes in the tsvector.</td>
<td>length('fat:2,4 cat:3 rat:5A':tsvector) → 3</td>
</tr>
<tr>
<td>numnode</td>
<td>Returns the number of lexemes plus operators in the tsquery.</td>
<td>numnode('fat &amp; rat</td>
</tr>
<tr>
<td>plainto_tsquery</td>
<td>([ config regconfig, ] query text )→ tsquery</td>
<td></td>
</tr>
<tr>
<td>Function</td>
<td>Description</td>
<td>Example(s)</td>
</tr>
<tr>
<td>---------------------------</td>
<td>-----------------------------------------------------------------------------</td>
<td>----------------------------------------------------------------------------</td>
</tr>
<tr>
<td>plainto_tsquery</td>
<td>Converts text to a tsquery, normalizing words according to the specified or default configuration. Any punctuation in the string is ignored (it does not determine query operators). The resulting query matches documents containing all non-stopwords in the text.</td>
<td>plainto_tsquery('english', 'The Fat Rats') → 'fat' &amp; 'rat'</td>
</tr>
<tr>
<td>phraseto_tsquery</td>
<td>Converts text to a tsquery, normalizing words according to the specified or default configuration. Any punctuation in the string is ignored (it does not determine query operators). The resulting query matches phrases containing all non-stopwords in the text.</td>
<td>phraseto_tsquery('english', 'The Fat Rats') → 'fat' &lt;-&gt; 'rat'</td>
</tr>
<tr>
<td>phraseto_tsquery</td>
<td>Converts text to a tsquery, normalizing words according to the specified or default configuration. Quoted word sequences are converted to phrase tests. The word “or” is understood as producing an OR operator, and a dash produces a NOT operator; other punctuation is ignored. This approximates the behavior of some common web search tools.</td>
<td>phraseto_tsquery('english', '&quot;fat rat&quot; or cat dog') → 'fat' &lt;-&gt; 'rat'</td>
</tr>
</tbody>
</table>
| querytree                 | Produces a representation of the indexable portion of a tsquery. A result that is empty or just \
T indicates a non-indexable query. | querytree('foo & ! bar':tsquery) → 'foo' |
| setweight                 | Assigns the specified weight to each element of the vector.                  | setweight('fat:2,4 cat:3 rat:5B':tsvector, 'A') → 'cat':3A 'fat':2A,4A 'rat':5A |
| setweight                 | Assigns the specified weight to elements of the vector that are listed in lexemes. | setweight('fat:2,4 cat:3 rat:5,6B':tsvector, 'A', '{cat,rat}') → 'cat':3A 'fat':2,4 'rat':5A,6A |
| strip                     | Removes positions and weights from the tsvector.                            | strip('fat:2,4 cat:3 rat:5A':tsvector) → 'cat' 'fat' 'rat' |
| to_tsquery                | Converts text to a tsquery, normalizing words according to the specified or default configuration. The words must be combined by valid tsquery operators. | to_tsquery('english', 'The & Fat & Rats') → 'fat' & 'rat' |
| to_tsvector               | Converts text to a tsvector, normalizing words according to the specified or default configuration. Position information is included in the result. | to_tsvector('english', 'The Fat Rats') → 'fat':2 'rat':3 |
| to_tsvector               | Converts each string value in the JSON document to a tsvector, normalizing words according to the specified or default configuration. The results are then concatenated in document order to produce the output. Position information is generated as though one | to_tsvector('english', 'The Fat Rats') → 'fat':2 'rat':3 |
Functions and Operators
Function
Description
Example(s)
stopword exists between each pair of string values. (Beware that “document order” of the
ﬁelds of a JSON object is implementation-dependent when the input is jsonb; observe the
diﬀerence in the examples.)
to_tsvector('english', '{"aa": "The Fat Rats", "b": "dog"}'::json)
→ 'dog':5
'fat':2 'rat':3
to_tsvector('english', '{"aa": "The Fat Rats", "b": "dog"}'::jsonb)
→
'dog':1 'fat':4 'rat':5
json_to_tsvector

( [ config regconfig, ] document json, filter jsonb ) → tsvector

jsonb_to_tsvector
( [ config regconfig, ] document jsonb, filter jsonb ) → tsvector
Selects each item in the JSON document that is requested by the filter and converts each
one to a tsvector, normalizing words according to the speciﬁed or default conﬁguration. The
results are then concatenated in document order to produce the output. Position information
is generated as though one stopword exists between each pair of selected items. (Beware that
“document order” of the ﬁelds of a JSON object is implementation-dependent when the input
is jsonb.) The filter must be a jsonb array containing zero or more of these keywords:
"string" (to include all string values), "numeric" (to include all numeric values), "boolean"
(to include all boolean values), "key" (to include all keys), or "all" (to include all the above).
As a special case, the filter can also be a simple JSON value that is one of these keywords.
json_to_tsvector('english', '{"a": "The Fat Rats", "b": 123}'::json,
'["string", "numeric"]') → '123':5 'fat':2 'rat':3
json_to_tsvector('english', '{"cat": "The Fat Rats", "dog": 123}'::json,
'"all"') → '123':9 'cat':1 'dog':7 'fat':4 'rat':5
ts_delete ( vector tsvector, lexeme text ) → tsvector
Removes any occurrence of the given lexeme from the vector.
ts_delete('fat:2,4 cat:3 rat:5A'::tsvector, 'fat')
→ 'cat':3 'rat':5A
ts_delete ( vector tsvector, lexemes text[] ) → tsvector
Removes any occurrences of the lexemes in lexemes from the vector.
ts_delete('fat:2,4 cat:3 rat:5A'::tsvector, ARRAY['fat','rat'])
ts_filter ( vector tsvector, weights "char"[] ) → tsvector
Selects only elements with the given weights from the vector.
ts_filter('fat:2,4 cat:3b,7c rat:5A'::tsvector, '{a,b}')
'rat':5A

→ 'cat':3

→ 'cat':3B

ts_headline ( [ config regconfig, ] document text, query tsquery [, options text ] ) → text
Displays, in an abbreviated form, the match(es) for the query in the document, which must be
raw text not a tsvector. Words in the document are normalized according to the speciﬁed
or default conﬁguration before matching to the query. Use of this function is discussed in
Section 12.3.4, which also describes the available options.
ts_headline('The fat cat ate the rat.', 'cat')
→ The fat <b>cat</b> ate the
rat.
ts_headline ( [ config regconfig, ] document json, query tsquery [, options text ] ) → text
ts_headline ( [ config regconfig, ] document jsonb, query tsquery [, options text ] ) → text
Displays, in an abbreviated form, match(es) for the query that occur in string values within
the JSON document. See Section 12.3.4 for more details.
ts_headline('{"cat":"raining cats and dogs"}'::jsonb, 'cat')
→ {"cat":
"raining <b>cats</b> and dogs"}

256


<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>

</tbody>
</table>

**Note**

All the text search functions that accept an optional regconfig argument will use the configuration specified by `default_text_search_config` when that argument is omitted.
The functions in Table 9.43 are listed separately because they are not usually used in everyday text searching operations. They are primarily helpful for development and debugging of new text search configurations.

Table 9.43. Text Search Debugging Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>ts_debug</td>
<td>Extracts and normalizes tokens from the document according to the specified or default text search configuration, and returns information about how each token was processed.</td>
<td>ts_debug('english', 'The Brightest supernovaes') → (asciiword,&quot;Word, all ASCII&quot;,The,{english_stem},english_stem,{}) ...</td>
</tr>
<tr>
<td>ts_lexize</td>
<td>Returns an array of replacement lexemes if the input token is known to the dictionary, or an empty array if the token is known to the dictionary but it is a stop word, or NULL if it is not a known word.</td>
<td>ts_lexize('english_stem', 'stars') → {star}</td>
</tr>
<tr>
<td>ts_parse</td>
<td>Extracts tokens from the document using the named parser. See Section 12.8.2 for details.</td>
<td>ts_parse('default', 'foo - bar') → (1,foo) ...</td>
</tr>
<tr>
<td>ts_parse</td>
<td>Extracts tokens from the document using a parser specified by OID. See Section 12.8.2 for details.</td>
<td>ts_parse(3722, 'foo - bar') → (1,foo) ...</td>
</tr>
<tr>
<td>ts_token_type</td>
<td>Returns a table that describes each type of token the named parser can recognize. See Section 12.8.2 for details.</td>
<td>ts_token_type('default') → (1,asciword,&quot;Word, all ASCII&quot;) ...</td>
</tr>
<tr>
<td>ts_token_type</td>
<td>Returns a table that describes each type of token a parser specified by OID can recognize. See Section 12.8.2 for details.</td>
<td>ts_token_type(3722) → (1,asciword,&quot;Word, all ASCII&quot;) ...</td>
</tr>
<tr>
<td>ts_stat</td>
<td>Executes the sqlquery, which must return a single tsvector column, and returns statistics about each distinct lexeme contained in the data. See Section 12.4.4 for details.</td>
<td>ts_stat('SELECT vector FROM apod') → (foo,10,15) ...</td>
</tr>
</tbody>
</table>

9.14. UUID Functions

PostgreSQL includes one function to generate a UUID:

```sql
gen_random_uuid () → uuid
```

This function returns a version 4 (random) UUID. This is the most commonly used type of UUID and is appropriate for most applications.
The uuid-ossp module provides additional functions that implement other standard algorithms for generating UUIDs.

PostgreSQL also provides the usual comparison operators shown in Table 9.1 for UUIDs.

9.15. XML Functions

The functions and function-like expressions described in this section operate on values of type xml. See Section 8.13 for information about the xml type. The function-like expressions xmlparse and xmlserialize for converting to and from type xml are documented there, not in this section.

Use of most of these functions requires Postgres Pro to have been built with configure --with-libxml.

9.15.1. Producing XML Content

A set of functions and function-like expressions is available for producing XML content from SQL data. As such, they are particularly suitable for formatting query results into XML documents for processing in client applications.

9.15.1.1. xmlcomment

xmlcomment ( text ) → xml

The function xmlcomment creates an XML value containing an XML comment with the specified text as content. The text cannot contain "--" or end with a "--", otherwise the resulting construct would not be a valid XML comment. If the argument is null, the result is null.

Example:

```sql
SELECT xmlcomment('hello');
```

xmlcomment
--------------
<!--hello-->

9.15.1.2. xmlconcat

xmlconcat ( xml [, ...] ) → xml

The function xmlconcat concatenates a list of individual XML values to create a single value containing an XML content fragment. Null values are omitted; the result is only null if there are no nonnull arguments.

Example:

```sql
SELECT xmlconcat('<abc/>', '<bar>foo</bar>');
```

xmlconcat
----------------------
<abc/><bar>foo</bar>

XML declarations, if present, are combined as follows. If all argument values have the same XML version declaration, that version is used in the result, else no version is used. If all argument values have the standalone declaration value “yes”, then that value is used in the result. If all argument values have a standalone declaration value and at least one is “no”, then that is used in the result. Else the result will have no standalone declaration. If the result is determined to require a standalone declaration but no version declaration, a version declaration with version 1.0 will be used because XML requires an XML declaration to contain a version declaration. Encoding declarations are ignored and removed in all cases.

Example:
9.15.1.3. \texttt{xmllement}

\texttt{xmllement} ( \texttt{NAME name}, \texttt{XMLATTRIBUTES} \{ \texttt{attvalue} \texttt{AS} \texttt{attname} \}, \ldots \} \rightarrow \texttt{xml}

The \texttt{xmllement} expression produces an XML element with the given name, attributes, and content. The \texttt{name} and \texttt{attname} items shown in the syntax are simple identifiers, not values. The \texttt{attvalue} and \texttt{content} items are expressions, which can yield any PostgreSQL data type. The argument(s) within \texttt{XMLATTRIBUTES} generate attributes of the XML element; the \texttt{content} value(s) are concatenated to form its content.

Examples:

\begin{verbatim}
SELECT xmlement(name foo);
\end{verbatim}

\begin{verbatim}
  xmlement
  ------------
  <foo/>
\end{verbatim}

\begin{verbatim}
SELECT xmlement(name foo, xmlattributes('xyz' as bar));
\end{verbatim}

\begin{verbatim}
  xmlement
  -------------
  <foo bar="xyz"/>
\end{verbatim}

\begin{verbatim}
SELECT xmlement(name foo, xmlattributes(current_date as bar), 'cont', 'ent');
\end{verbatim}

\begin{verbatim}
  xmlement
  -------------------------------------
  <foo bar="2007-01-26">content</foo>
\end{verbatim}

Element and attribute names that are not valid XML names are escaped by replacing the offending characters by the sequence \_\texttt{HHHH}, where \texttt{HHHH} is the character's Unicode codepoint in hexadecimal notation. For example:

\begin{verbatim}
SELECT xmlement(name "foo$bar", xmlattributes('xyz' as "a\&b"));
\end{verbatim}

\begin{verbatim}
  xmlement
  -------------------
  <foo_x0024_bar a_x0026_b="xyz"/>
\end{verbatim}

An explicit attribute name need not be specified if the attribute value is a column reference, in which case the column's name will be used as the attribute name by default. In other cases, the attribute must be given an explicit name. So this example is valid:

\begin{verbatim}
CREATE TABLE test (a xml, b xml);
SELECT xmlement(name test, xmlattributes(a, b)) FROM test;
\end{verbatim}

But these are not:

\begin{verbatim}
SELECT xmlement(name test, xmlattributes('constant'), a, b) FROM test;
SELECT xmlement(name test, xmlattributes(func(a, b))) FROM test;
\end{verbatim}

Element content, if specified, will be formatted according to its data type. If the content is itself of type \texttt{xml}, complex XML documents can be constructed. For example:
SELECT xmlelement(name foo, xmlattributes('xyz' as bar),
    xmlelement(name abc),
    xmlcomment('test'),
    xmlelement(name xyz));

---

<foo bar="xyz"><abc/></foo><test/></foo>

Content of other types will be formatted into valid XML character data. This means in particular that the characters <, >, and & will be converted to entities. Binary data (data type bytea) will be represented in base64 or hex encoding, depending on the setting of the configuration parameter xmlbinary. The particular behavior for individual data types is expected to evolve in order to align the Postgres Pro mappings with those specified in SQL:2006 and later, as discussed in Section D.3.1.3.

9.15.1.4. xmlforest

xmlforest ( content [ AS name ] [, ... ] ) → xml

The xmlforest expression produces an XML forest (sequence) of elements using the given names and content. As for xmlelement, each name must be a simple identifier, while the content expressions can have any data type.

Examples:

SELECT xmlforest('abc' AS foo, 123 AS bar);

xmlforest
-------------------
<foo>abc</foo><bar>123</bar>

SELECT xmlforest(table_name, column_name)
FROM information_schema.columns
WHERE table_schema = 'pg_catalog';

xmlforest
-------------------
<table_name>pg_authid</table_name><column_name>rolname</column_name>
<table_name>pg_authid</table_name><column_name>rolsuper</column_name>
...

As seen in the second example, the element name can be omitted if the content value is a column reference, in which case the column name is used by default. Otherwise, a name must be specified.

Element names that are not valid XML names are escaped as shown for xmlelement above. Similarly, content data is escaped to make valid XML content, unless it is already of type xml.

Note that XML forests are not valid XML documents if they consist of more than one element, so it might be useful to wrap xmlforest expressions in xmlelement.

9.15.1.5. xmlpi

xmlpi ( NAME name [, content ] ) → xml

The xmlpi expression creates an XML processing instruction. As for xmlelement, the name must be a simple identifier, while the content expression can have any data type. The content, if present, must not contain the character sequence ?>.

Example:
9.15.1.6. xmlroot
xmlroot ( xml, VERSION {text|NO VALUE} [, STANDALONE {YES|NO|NO VALUE} ] ) → xml

The xmlroot expression alters the properties of the root node of an XML value. If a version is specified, it replaces the value in the root node's version declaration; if a standalone setting is specified, it replaces the value in the root node's standalone declaration.

SELECT xmlroot(xmlparse(document '<?xml version="1.1"?><content>abc</content>'), version '1.0', standalone yes);

xmlroot
----------------------------------------
<?xml version="1.0" standalone="yes"?><content>abc</content>

9.15.1.7. xmlagg
xmlagg ( xml ) → xml

The function xmlagg is, unlike the other functions described here, an aggregate function. It concatenates the input values to the aggregate function call, much like xmlconcat does, except that concatenation occurs across rows rather than across expressions in a single row. See Section 9.21 for additional information about aggregate functions.

Example:
CREATE TABLE test (y int, x xml);
INSERT INTO test VALUES (1, '<foo>abc</foo>');
INSERT INTO test VALUES (2, '<bar/>');
SELECT xmlagg(x) FROM test;
xmlagg
----------------------
<foo>abc</foo><bar/>

To determine the order of the concatenation, an ORDER BY clause may be added to the aggregate call as described in Section 4.2.7. For example:

SELECT xmlagg(x ORDER BY y DESC) FROM test;
xmlagg
----------------------
<bar/><foo>abc</foo>

The following non-standard approach used to be recommended in previous versions, and may still be useful in specific cases:

SELECT xmlagg(x) FROM (SELECT * FROM test ORDER BY y DESC) AS tab;
xmlagg
----------------------
<bar/><foo>abc</foo>

9.15.2. XML Predicates

The expressions described in this section check properties of xml values.
9.15.2.1. IS DOCUMENT

xml IS DOCUMENT → boolean

The expression IS DOCUMENT returns true if the argument XML value is a proper XML document, false if it is not (that is, it is a content fragment), or null if the argument is null. See Section 8.13 about the difference between documents and content fragments.

9.15.2.2. IS NOT DOCUMENT

xml IS NOT DOCUMENT → boolean

The expression IS NOT DOCUMENT returns false if the argument XML value is a proper XML document, true if it is not (that is, it is a content fragment), or null if the argument is null.

9.15.2.3. XMLEXISTS

XMLEXISTS ( text PASSING [BY {REF|VALUE}] xml [BY {REF|VALUE}] ) → boolean

The function xmlexists evaluates an XPath 1.0 expression (the first argument), with the passed XML value as its context item. The function returns false if the result of that evaluation yields an empty node-set, true if it yields any other value. The function returns null if any argument is null. A nonnull value passed as the context item must be an XML document, not a content fragment or any non-XML value.

Example:

```
SELECT xmlexists('//town[text() = ''Toronto'']' PASSING BY VALUE
  '<towns><town>Toronto</town><town>Ottawa</town></towns>');
```

xmlexists
-----------
  t
(1 row)

The BY REF and BY VALUE clauses are accepted in Postgres Pro, but are ignored, as discussed in Section D.3.2.

In the SQL standard, the xmlexists function evaluates an expression in the XML Query language, but Postgres Pro allows only an XPath 1.0 expression, as discussed in Section D.3.1.

9.15.2.4. xml_is_well_formed

xml_is_well_formed ( text ) → boolean
xml_is_well_formed_document ( text ) → boolean
xml_is_well_formed_content ( text ) → boolean

These functions check whether a text string represents well-formed XML, returning a Boolean result. xml_is_well_formed_document checks for a well-formed document, while xml_is_well_formed_content checks for well-formed content. xml_is_well_formed does the former if the xmloption configuration parameter is set to DOCUMENT, or the latter if it is set to CONTENT. This means that xml_is_well_formed is useful for seeing whether a simple cast to type xml will succeed, whereas the other two functions are useful for seeing whether the corresponding variants of XMLPARSE will succeed.

Examples:

```
SET xmloption TO DOCUMENT;
SELECT xml_is_well_formed('<>');
xml_is_well_formed
-------------
  f
```
Functions and Operators

{1 row)

SELECT xml_is_well_formed('<abc/>');
 xml_is_well_formed
--------------------
t
(1 row)

SET xmloption TO CONTENT;
SELECT xml_is_well_formed('abc');
 xml_is_well_formed
--------------------
t
(1 row)

SELECT xml_is_well_formed_document('<pg:foo xmlns:pg="http://postgresql.org/stuff">bar</pg:foo>');
 xml_is_well_formed_document
-----------------------------
t
(1 row)

SELECT xml_is_well_formed_document('<pg:foo xmlns:pg="http://postgresql.org/stuff">bar</my:foo>');</n
 xml_is_well_formed_document
-----------------------------
f
(1 row)

The last example shows that the checks include whether namespaces are correctly matched.

9.15.3. Processing XML

To process values of data type xml, Postgres Pro offers the functions xpath and xpath_exists, which evaluate XPath 1.0 expressions, and the XMLTABLE table function.

9.15.3.1. xpath

$\text{xpath} \ (\text{xpath text, xml xml} \ [, \text{nsarray text[]} \ ] \ ) \rightarrow \text{xml[]}$

The function xpath evaluates the XPath 1.0 expression xpath (given as text) against the XML value xml. It returns an array of XML values corresponding to the node-set produced by the XPath expression. If the XPath expression returns a scalar value rather than a node-set, a single-element array is returned.

The second argument must be a well formed XML document. In particular, it must have a single root node element.

The optional third argument of the function is an array of namespace mappings. This array should be a two-dimensional text array with the length of the second axis being equal to 2 (i.e., it should be an array of arrays, each of which consists of exactly 2 elements). The first element of each array entry is the namespace name (alias), the second the namespace URI. It is not required that aliases provided in this array be the same as those being used in the XML document itself (in other words, both in the XML document and in the xpath function context, aliases are local).

Example:

 ARRAY[ARRAY['my', 'http://example.com']]);
Functions and Operators
xpath
-------{test}
(1 row)
To deal with default (anonymous) namespaces, do something like this:
SELECT xpath('//mydefns:b/text()', '<a xmlns="http://example.com"><b>test</b></a>',
ARRAY[ARRAY['mydefns', 'http://example.com']]);
xpath
-------{test}
(1 row)

9.15.3.2. xpath_exists
xpath_exists ( xpath text, xml xml [, nsarray text[] ] ) → boolean
The function xpath_exists is a specialized form of the xpath function. Instead of returning the individual
XML values that satisfy the XPath 1.0 expression, this function returns a Boolean indicating whether the
query was satisﬁed or not (speciﬁcally, whether it produced any value other than an empty node-set).
This function is equivalent to the XMLEXISTS predicate, except that it also oﬀers support for a namespace
mapping argument.
Example:
ARRAY[ARRAY['my', 'http://example.com']]);
xpath_exists
-------------t
(1 row)

9.15.3.3. xmltable
XMLTABLE (
[ XMLNAMESPACES ( namespace_uri AS namespace_name [, ...] ), ]
row_expression PASSING [BY {REF|VALUE}] document_expression [BY {REF|VALUE}]
COLUMNS name { type [PATH column_expression] [DEFAULT default_expression] [NOT NULL
| NULL]
| FOR ORDINALITY }
[, ...]
) → setof record
The xmltable expression produces a table based on an XML value, an XPath ﬁlter to extract rows, and
a set of column deﬁnitions. Although it syntactically resembles a function, it can only appear as a table
in a query's FROM clause.
The optional XMLNAMESPACES clause gives a comma-separated list of namespace deﬁnitions, where each
namespace_uri is a text expression and each namespace_name is a simple identiﬁer. It speciﬁes the XML
namespaces used in the document and their aliases. A default namespace speciﬁcation is not currently
supported.
The required row_expression argument is an XPath 1.0 expression (given as text) that is evaluated,
passing the XML value document_expression as its context item, to obtain a set of XML nodes.
These nodes are what xmltable transforms into output rows. No rows will be produced if the
document_expression is null, nor if the row_expression produces an empty node-set or any value other
than a node-set.
265


document_expression provides the context item for the row_expression. It must be a well-formed XML document; fragments/forests are not accepted. The BY REF and BY VALUE clauses are accepted but ignored, as discussed in Section D.3.2.

In the SQL standard, the xmltable function evaluates expressions in the XML Query language, but Postgres Pro allows only XPath 1.0 expressions, as discussed in Section D.3.1.

The required COLUMNS clause specifies the column(s) that will be produced in the output table. See the syntax summary above for the format. A name is required for each column, as is a data type (unless FOR ORDINALITY is specified, in which case type integer is implicit). The path, default and nullability clauses are optional.

A column marked FOR ORDINALITY will be populated with row numbers, starting with 1, in the order of nodes retrieved from the row_expression’s result node-set. At most one column may be marked FOR ORDINALITY.

**Note**

XPath 1.0 does not specify an order for nodes in a node-set, so code that relies on a particular order of the results will be implementation-dependent. Details can be found in Section D.3.1.2.

The column_expression for a column is an XPath 1.0 expression that is evaluated for each row, with the current node from the row_expression result as its context item, to find the value of the column. If no column_expression is given, then the column name is used as an implicit path.

If a column's XPath expression returns a non-XML value (which is limited to string, boolean, or double in XPath 1.0) and the column has a Postgres Pro type other than xml, the column will be set as if by assigning the value's string representation to the Postgres Pro type. (If the value is a boolean, its string representation is taken to be 1 or 0 if the output column's type category is numeric, otherwise true or false.)

If a column’s XPath expression returns a non-empty set of XML nodes and the column’s Postgres Pro type is xml, the column will be assigned the expression result exactly, if it is of document or content form.  

A non-XML result assigned to an xml output column produces content, a single text node with the string value of the result. An XML result assigned to a column of any other type may not have more than one node, or an error is raised. If there is exactly one node, the column will be set as if by assigning the node's string value (as defined for the XPath 1.0 string function) to the Postgres Pro type.

The string value of an XML element is the concatenation, in document order, of all text nodes contained in that element and its descendants. The string value of an element with no descendant text nodes is an empty string (not NULL). Any xsi:nil attributes are ignored. Note that the whitespace-only text() node between two non-text elements is preserved, and that leading whitespace on a text() node is not flattened. The XPath 1.0 string function may be consulted for the rules defining the string value of other XML node types and non-XML values.

The conversion rules presented here are not exactly those of the SQL standard, as discussed in Section D.3.1.3.

If the path expression returns an empty node-set (typically, when it does not match) for a given row, the column will be set to NULL, unless a default_expression is specified; then the value resulting from evaluating that expression is used.

A default_expression, rather than being evaluated immediately when xmltable is called, is evaluated each time a default is needed for the column. If the expression qualifies as stable or immutable, the

---

1 A result containing more than one element node at the top level, or non-whitespace text outside of an element, is an example of content form. An XPath result can be of neither form, for example if it returns an attribute node selected from the element that contains it. Such a result will be put into content form with each such disallowed node replaced by its string value, as defined for the XPath 1.0 string function.
Functions and Operators

repeat evaluation may be skipped. This means that you can usefully use volatile functions like nextval in default_expression.

Columns may be marked NOT NULL. If the column_expression for a NOT NULL column does not match anything and there is no DEFAULT or the default_expression also evaluates to null, an error is reported.

Examples:

```
CREATE TABLE xmldata AS SELECT xml $$
<ROWS>
    <ROW id="1">
        <COUNTRY_ID>AU</COUNTRY_ID>
        <COUNTRY_NAME>Australia</COUNTRY_NAME>
    </ROW>
    <ROW id="5">
        <COUNTRY_ID>JP</COUNTRY_ID>
        <COUNTRY_NAME>Japan</COUNTRY_NAME>
        <PREMIER_NAME>Shinzo Abe</PREMIER_NAME>
        <SIZE unit="sq_mi">145935</SIZE>
    </ROW>
    <ROW id="6">
        <COUNTRY_ID>SG</COUNTRY_ID>
        <COUNTRY_NAME>Singapore</COUNTRY_NAME>
        <SIZE unit="sq_km">697</SIZE>
    </ROW>
</ROWS>
$$ AS data;
```

```
SELECT xmltable.*
FROM xmldata,
XMLTABLE('//ROWS/ROW'
    PASSING data
    COLUMNS id int PATH '@id',
    ordinality FOR ORDINALITY,
    "COUNTRY_NAME" text,
    country_id text PATH 'COUNTRY_ID',
    size_sq_km float PATH 'SIZE[@unit = "sq_km"]',
    size_other text PATH
        'concat(SIZE[@unit="sq_km"], " ", SIZE[@unit="sq_km"]/@unit)',
    premier_name text PATH 'PREMIER_NAME' DEFAULT 'not specified');
```

<table>
<thead>
<tr>
<th>id</th>
<th>ordinality</th>
<th>COUNTRY_NAME</th>
<th>country_id</th>
<th>size_sq_km</th>
<th>size_other</th>
<th>premier_name</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>Australia</td>
<td>AU</td>
<td></td>
<td></td>
<td>not specified</td>
</tr>
<tr>
<td>5</td>
<td>2</td>
<td>Japan</td>
<td>JP</td>
<td></td>
<td>145935 sq_mi</td>
<td>Shinzo Abe</td>
</tr>
<tr>
<td>6</td>
<td>3</td>
<td>Singapore</td>
<td>SG</td>
<td>697</td>
<td></td>
<td>not specified</td>
</tr>
</tbody>
</table>

The following example shows concatenation of multiple text() nodes, usage of the column name as XPath filter, and the treatment of whitespace, XML comments and processing instructions:

```
CREATE TABLE xmlelements AS SELECT xml $$
<root>
    <element> Hello<!-- xyxxz -->2a2<?aaaaa?> <!--x--> bbb<x>xxx</x> CC </element>
$$ AS data;
```
$$ AS data;
SELECT xmltable.*
  FROM xmlelements, XMLTABLE('/root' PASSING data COLUMNS element text);

-------------------------
Hello2a2   bbbxxxCC

The following example illustrates how the XMLNAMESPACES clause can be used to specify a list of namespaces used in the XML document as well as in the XPath expressions:

WITH xmldata(data) AS (VALUES ('<example xmlns="http://example.com/myns" xmlns:B="http://example.com/b">
<item foo="1" B:bar="2"/>
<item foo="3" B:bar="4"/>
<item foo="4" B:bar="5"/>
</example>''::xml)
)
SELECT xmltable.*
  FROM XMLTABLE(XMLNAMESPACES('http://example.com/myns' AS x,
   'http://example.com/b' AS "B"),
   '/x:example/x:item'
  PASSING (SELECT data FROM xmldata)
COLUMNS foo int PATH '@foo',
   bar int PATH '@B:bar');

foo | bar
-----+-----
1 |   2
3 |   4
4 |   5
(3 rows)

9.15.4. Mapping Tables to XML

The following functions map the contents of relational tables to XML values. They can be thought of as XML export functionality:

\[\text{table_to_xml (table regclass, nulls boolean, tableforest boolean, targetns text) } \rightarrow \text{xml}\]

\[\text{query_to_xml (query text, nulls boolean, tableforest boolean, targetns text) } \rightarrow \text{xml}\]

\[\text{cursor_to_xml (cursor refcursor, count integer, nulls boolean, tableforest boolean, targetns text) } \rightarrow \text{xml}\]

\text{table_to_xml} \text{ maps the content of the named table, passed as parameter table. The regclass type accepts strings identifying tables using the usual notation, including optional schema qualification and double quotes (see Section 8.19 for details). query_to_xml} \text{ executes the query whose text is passed as parameter query and maps the result set. cursor_to_xml} \text{ fetches the indicated number of rows from the cursor specified by the parameter cursor. This variant is recommended if large tables have to be mapped, because the result value is built up in memory by each function.}

If \text{tableforest} \text{ is false, then the resulting XML document looks like this:

\text{<tablename>}
  \text{<row>}
    \text{<columnname1>data</columnname1>}
    \text{<columnname2>data</columnname2>}
  \text{</row>}
\text{</tablename>
If tableforest is true, the result is an XML content fragment that looks like this:

```xml
<tablename>
  <columnname1>data</columnname1>
  <columnname2>data</columnname2>
</tablename>
```

If no table name is available, that is, when mapping a query or a cursor, the string table is used in the first format, row in the second format.

The choice between these formats is up to the user. The first format is a proper XML document, which will be important in many applications. The second format tends to be more useful in the cursor_to_xml function if the result values are to be reassembled into one document later on. The functions for producing XML content discussed above, in particular xmlelement, can be used to alter the results to taste.

The data values are mapped in the same way as described for the function xmlelement above.

The parameter nulls determines whether null values should be included in the output. If true, null values in columns are represented as:

```xml
<columnname xsi:nil="true"/>
```

where xsi is the XML namespace prefix for XML Schema Instance. An appropriate namespace declaration will be added to the result value. If false, columns containing null values are simply omitted from the output.

The parameter targetns specifies the desired XML namespace of the result. If no particular namespace is wanted, an empty string should be passed.

The following functions return XML Schema documents describing the mappings performed by the corresponding functions above:

```c
table_to_xmlschema ( table regclass, nulls boolean, tableforest boolean, targetns text ) → xml
query_to_xmlschema ( query text, nulls boolean, tableforest boolean, targetns text ) → xml
cursor_to_xmlschema ( cursor refcursor, nulls boolean, tableforest boolean, targetns text ) → xml
```

It is essential that the same parameters are passed in order to obtain matching XML data mappings and XML Schema documents.

The following functions produce XML data mappings and the corresponding XML Schema in one document (or forest), linked together. They can be useful where self-contained and self-describing results are wanted:

```c
table_to_xml_and_xmlschema ( table regclass, nulls boolean, tableforest boolean, targetns text ) → xml
```

269
Functions and Operators

\[
\text{query\_to\_xml\_and\_xmlschema ( query text, nulls boolean, tableforest boolean, targetns text ) \rightarrow xml}
\]

In addition, the following functions are available to produce analogous mappings of entire schemas or the entire current database:

\[
\text{schema\_to\_xml ( schema name, nulls boolean, tableforest boolean, targetns text ) \rightarrow xml}
\]

\[
\text{schema\_to\_xmlschema ( schema name, nulls boolean, tableforest boolean, targetns text ) \rightarrow xml}
\]

\[
\text{schema\_to\_xml\_and\_xmlschema ( schema name, nulls boolean, tableforest boolean, targetns text ) \rightarrow xml}
\]

\[
\text{database\_to\_xml ( nulls boolean, tableforest boolean, targetns text ) \rightarrow xml}
\]

\[
\text{database\_to\_xmlschema ( nulls boolean, tableforest boolean, targetns text ) \rightarrow xml}
\]

\[
\text{database\_to\_xml\_and\_xmlschema ( nulls boolean, tableforest boolean, targetns text ) \rightarrow xml}
\]

These functions ignore tables that are not readable by the current user. The database-wide functions additionally ignore schemas that the current user does not have USAGE (lookup) privilege for.

Note that these potentially produce a lot of data, which needs to be built up in memory. When requesting content mappings of large schemas or databases, it might be worthwhile to consider mapping the tables separately instead, possibly even through a cursor.

The result of a schema content mapping looks like this:

\[
<schemaname>
\text{table1-mapping}
\text{table2-mapping}
\ldots
</schemaname>
\]

where the format of a table mapping depends on the \textit{tableforest} parameter as explained above.

The result of a database content mapping looks like this:

\[
<dbname>
\text{<schema1name>}
\ldots
</schema1name>
\text{<schema2name>}
\ldots
</schema2name>
\ldots
</dbname>
\]

where the schema mapping is as above.
As an example of using the output produced by these functions, Example 9.1 shows an XSLT stylesheet that converts the output of `table_to_xml_and_xmlschema` to an HTML document containing a tabular rendition of the table data. In a similar manner, the results from these functions can be converted into other XML-based formats.

**Example 9.1. XSLT Stylesheet for Converting SQL/XML Output to HTML**

```xml
<?xml version="1.0"?>
<xsl:stylesheet version="1.0"
    xmlns:xsl="http://www.w3.org/1999/XSL/Transform"
    xmlns:xsd="http://www.w3.org/2001/XMLSchema"
    xmlns="http://www.w3.org/1999/xhtml">
    <xsl:output method="xml"
        doctype-system="http://www.w3.org/TR/xhtml1/DTD/xhtml1-strict.dtd"
        doctype-public="-//W3C/DTD XHTML 1.0 Strict//EN"
        indent="yes"/>
    <xsl:template match="/">
        <xsl:variable name="schema" select="//xsd:schema"/>
        <xsl:variable name="tabletypename"
            select="$schema/xsd:element[@name=name(current())]/@type"/>
        <xsl:variable name="rowtypename"
            select="$schema/xsd:complexType[@name=$tabletypename]/xsd:sequence/xsd:element[@name='row']/@type"/>
        <html>
            <head>
                <title><xsl:value-of select="name(current())"/></title>
            </head>
            <body>
                <table>
                    <tr>
                        <xsl:for-each select="$schema/xsd:complexType[@name=$rowtypename]/xsd:sequence/xsd:element[@name]">
                            <th><xsl:value-of select="."/></th>
                        </xsl:for-each>
                    </tr>
                    <xsl:for-each select="row">
                        <tr>
                            <xsl:for-each select="*" select="."/>
                            <td><xsl:value-of select="."/></td>
                        </xsl:for-each>
                    </xsl:for-each>
                </table>
            </body>
        </html>
    </xsl:template>
</xsl:stylesheet>
```

9.16. JSON Functions and Operators

This section describes:

- functions and operators for processing and creating JSON data
To learn more about the SQL/JSON standard, see sqltr-19075-6. For details on JSON types supported in Postgres Pro, see Section 8.14.

### 9.16.1. Processing and Creating JSON Data

Table 9.44 shows the operators that are available for use with JSON data types (see Section 8.14). In addition, the usual comparison operators shown in Table 9.1 are available for jsonb, though not for json. The comparison operators follow the ordering rules for B-tree operations outlined in Section 8.14.4.

#### Table 9.44. json and jsonb Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
</table>
| json -> integer → json | Extracts \( n \)’th element of JSON array (array elements are indexed from zero, but negative integers count from the end). | '[["a":"foo"],{"b":"bar"},{"c":"baz"}]'::json -> 2 \( \rightarrow \{"c":"baz"\} \)
| jsonb -> integer → jsonb | Extracts JSON object field with the given key. | '{"a": {"b":"foo"}}'::json -> 'a' \( \rightarrow \{"b":"foo"\} \)
| json -> text → json | Extracts JSON sub-object at the specified path, where path elements can be either field keys or array indexes. | '{"a": {"b": ["foo","bar"]}}'::json -> '{a,b,1}' \( \rightarrow \"bar"\) |
| jsonb -> text[] → jsonb | Extracts JSON sub-object at the specified path as text. | '{"a": {"b": ["foo","bar"]}}'::jsonb #> '{a,b,1}' \( \rightarrow \text{bar}\) |

### Note

The field/element/path extraction operators return NULL, rather than failing, if the JSON input does not have the right structure to match the request; for example if no such key or array element exists.
Some further operators exist only for `jsonb`, as shown in Table 9.45. Section 8.14.4 describes how these operators can be used to effectively search indexed `jsonb` data.

**Table 9.45. Additional `jsonb` Operators**

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>jsonb @&gt; jsonb</code> → <code>boolean</code></td>
<td>Does the first JSON value contain the second? (See Section 8.14.3 for details about containment.)</td>
<td><code>{&quot;a&quot;:1, &quot;b&quot;:2}</code>::jsonb @&gt; <code>{&quot;b&quot;:2}</code>::jsonb → t</td>
</tr>
<tr>
<td><code>jsonb &lt;@ jsonb</code> → <code>boolean</code></td>
<td>Is the first JSON value contained in the second?</td>
<td><code>{&quot;b&quot;:2}</code>::jsonb &lt;@ <code>{&quot;a&quot;:1, &quot;b&quot;:2}</code>::jsonb → t</td>
</tr>
<tr>
<td><code>jsonb ? text</code> → <code>boolean</code></td>
<td>Does the text string exist as a top-level key or array element within the JSON value?</td>
<td><code>{&quot;a&quot;:1, &quot;b&quot;:2}</code>::jsonb ? 'b' → t</td>
</tr>
<tr>
<td>`jsonb ?</td>
<td>text[]<code>→</code>boolean`</td>
<td>Do any of the strings in the text array exist as top-level keys or array elements?</td>
</tr>
<tr>
<td><code>jsonb ?&amp; text[]</code> → <code>boolean</code></td>
<td>Do all of the strings in the text array exist as top-level keys or array elements?</td>
<td><code>[&quot;a&quot;, &quot;b&quot;, &quot;c&quot;]</code>::jsonb ?&amp; array['a', 'b'] → t</td>
</tr>
<tr>
<td>`jsonb</td>
<td></td>
<td>jsonb<code>→</code>jsonb`</td>
</tr>
<tr>
<td><code>jsonb - text</code> → <code>jsonb</code></td>
<td>Deletes a key (and its value) from a JSON object, or matching string value(s) from a JSON array.</td>
<td><code>{&quot;a&quot;: &quot;b&quot;, &quot;c&quot;: &quot;d&quot;}</code>::jsonb - 'a' → {&quot;c&quot;: &quot;d&quot;}</td>
</tr>
<tr>
<td><code>jsonb - text[]</code> → <code>jsonb</code></td>
<td>Deletes all matching keys or array elements from the left operand.</td>
<td><code>{&quot;a&quot;: &quot;b&quot;, &quot;c&quot;: &quot;d&quot;}</code>::jsonb - <code>{a,c}</code>::text[] → {}</td>
</tr>
</tbody>
</table>

273
### Functions and Operators

**Operator**

**Description**

Deleters the array element with specified index (negative integers count from the end).

*Throws an error if JSON value is not an array.*

\[
'\{a\}, \{b\}'::jsonb \rightarrow \{a\}
\]

**Example(s)**

\[
'\["a", \"b"\]::jsonb - 1 \rightarrow \{a\}
\]

---

**Operator**

**Description**

Deletes the field or array element at the specified path, where path elements can be either field keys or array indexes.

\[
'\{a\}, \{b\}'::jsonb \rightarrow \{a\}, \{\}
\]

**Example(s)**

\[
'\{a\}, \{b\}'::jsonb \rightarrow \{a\}, \{\}
\]

---

**Operator**

**Description**

Does JSON path return any item for the specified JSON value?

\[
'\{a\}:\{1,2,3,4,5\}'::jsonb \rightarrow \{\}
\]

**Example(s)**

\[
'\{a\}:\{1,2,3,4,5\}'::jsonb \rightarrow \{\}
\]

---

**Operator**

**Description**

Returns the result of a JSON path predicate check for the specified JSON value. Only the first item of the result is taken into account. If the result is not Boolean, then NULL is returned.

\[
'\{a\}:\{1,2,3,4,5\}'::jsonb \rightarrow \{\}
\]

**Example(s)**

\[
'\{a\}:\{1,2,3,4,5\}'::jsonb \rightarrow \{\}
\]

---

**Note**

The **jsonpath** operators `@?` and `@@` suppress the following errors: missing object field or array element, unexpected JSON item type, datetime and numeric errors. The **jsonpath**-related functions described below can also be told to suppress these types of errors. This behavior might be helpful when searching JSON document collections of varying structure.

---

**Table 9.46** shows the functions that are available for constructing **json** and **jsonb** values.

---

**Table 9.46. JSON Creation Functions**

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>to_json</code></td>
<td>(anyelement) → json</td>
<td><code>to_json('Fred said &quot;Hi.&quot;::text) → &quot;Fred said \&quot;Hi.\&quot;&quot;</code></td>
</tr>
<tr>
<td><code>to_jsonb</code></td>
<td>(anyelement) → jsonb</td>
<td><code>to_jsonb(row(42, 'Fred said &quot;Hi.&quot;::text)) → {f1: 42, &quot;f2&quot;: &quot;Fred said \&quot;Hi.\&quot;&quot;}</code></td>
</tr>
<tr>
<td><code>array_to_json</code></td>
<td>(anyarray [, boolean ]) → json</td>
<td><code>array_to_json('{{1,5},{99,100}}'::int[]) → [[1,5],[99,100]]</code></td>
</tr>
<tr>
<td><code>row_to_json</code></td>
<td>(record [, boolean ]) → json</td>
<td><code>row_to_json()</code></td>
</tr>
</tbody>

</table>
| select * from json_object_keys('"f1":"abc","f2":{"f3":"a", "f4":"b"}') | →
| json_object_keys | ------------------ |
| f1 | f2 |

**json_populate_record** (base anyelement, from_json json) → anyelement

**jsonb_populate_record** (base anyelement, from_json jsonb) → anyelement

Expands the top-level JSON object to a row having the composite type of the base argument. The JSON object is scanned for fields whose names match column names of the output row type, and their values are inserted into those columns of the output. (Fields that do not correspond to any output column name are ignored.) In typical use, the value of base is just NULL, which means that any output columns that do not match any object field will be filled with nulls. However, if base isn't NULL then the values it contains will be used for unmatched columns.

To convert a JSON value to the SQL type of an output column, the following rules are applied in sequence:

- A JSON null value is converted to an SQL null in all cases.
- If the output column is of type json or jsonb, the JSON value is just reproduced exactly.
- If the output column is a composite (row) type, and the JSON value is a JSON object, the fields of the object are converted to columns of the output row type by recursive application of these rules.
- Likewise, if the output column is an array type and the JSON value is a JSON array, the elements of the JSON array are converted to elements of the output array by recursive application of these rules.
- Otherwise, if the JSON value is a string, the contents of the string are fed to the input conversion function for the column's data type.
- Otherwise, the ordinary text representation of the JSON value is fed to the input conversion function for the column's data type.

While the example below uses a constant JSON value, typical use would be to reference a json or jsonb column laterally from another table in the query's FROM clause. Writing json_populate_record in the FROM clause is good practice, since all of the extracted columns are available for use without duplicate function calls.

```sql
create type subrowtype as (d int, e text); create type myrowtype as (a int, b text[], c subrowtype);
select * from json_populate_record(null::myrowtype, '{"a": 1, "b": ["2", "a b"], "c": {"d": 4, "e": "a b c"}, "x": "foo"}')

<table>
<thead>
<tr>
<th>a</th>
<th>b</th>
<th>c</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>{2,&quot;a b&quot;}</td>
<td>(4,&quot;a b c&quot;)</td>
</tr>
</tbody>
</table>
```

**json_populate_recordset** (base anyelement, from_json json) → setof anyelement

**jsonb_populate_recordset** (base anyelement, from_json jsonb) → setof anyelement

Expands the top-level JSON array of objects to a set of rows having the composite type of the base argument. Each element of the JSON array is processed as described above for jsonb_populate_record.

```sql
create type twoints as (a int, b int);
select * from json_populate_recordset(null::twoints, '{"a":1,"b":2},
{"a":3,"b":4}}')

json_to_record

( json ) → record

jsonb_to_record
( jsonb ) → record
Expands the top-level JSON object to a row having the composite type deﬁned by an AS
clause. (As with all functions returning record, the calling query must explicitly deﬁne the
structure of the record with an AS clause.) The output record is ﬁlled from ﬁelds of the JSON
object, in the same way as described above for json[b]_populate_record . Since there is
no input record value, unmatched columns are always ﬁlled with nulls.
create type myrowtype as (a int, b text);
select * from json_to_record('{"a":1,"b":[1,2,3],"c":[1,2,3],
"e":"bar","r": {"a": 123, "b": "a b c"}}') as x(a int, b text, c int[],
d text, r myrowtype) →
a |
b
|
c
| d |
r
---+---------+---------+---+--------------1 | [1,2,3] | {1,2,3} |
| (123,"a b c")
json_to_recordset

( json ) → setof record

jsonb_to_recordset
( jsonb ) → setof record
Expands the top-level JSON array of objects to a set of rows having the composite type
deﬁned by an AS clause. (As with all functions returning record, the calling query must
explicitly deﬁne the structure of the record with an AS clause.) Each element of the JSON
array is processed as described above for json[b]_populate_record .
select * from json_to_recordset('[{"a":1,"b":"foo"}, {"a":"2",
"c":"bar"}]') as x(a int, b text)
→
a | b
---+----1 | foo
2 |
jsonb_set ( target jsonb, path text[], new_value jsonb [, create_if_missing
boolean ] ) →
jsonb
Returns target with the item designated by path replaced by new_value , or with new_
value added if create_if_missing
is true (which is the default) and the item designated
by path does not exist. All earlier steps in the path must exist, or the target is returned
unchanged. As with the path oriented operators, negative integers that appear in the path
count from the end of JSON arrays. If the last path step is an array index that is out of range,
and create_if_missing
is true, the new value is added at the beginning of the array if the
index is negative, or at the end of the array if it is positive.
jsonb_set('[{"f1":1,"f2":null},2,null,3]', '{0,f1}', '[2,3,4]',
false) → [{"f1": [2, 3, 4], "f2": null}, 2, null, 3]
jsonb_set('[{"f1":1,"f2":null},2]', '{0,f3}', '[2,3,4]')
"f2": null, "f3": [2, 3, 4]}, 2]

→ [{"f1": 1,

jsonb_set_lax
( target jsonb, path text[], new_value jsonb [, create_if_missing
boolean
[, null_value_treatment
text ]] ) → jsonb
If new_value is not NULL, behaves identically to jsonb_set . Otherwise behaves according
to the value of null_value_treatment
which must be one of 'raise_exception' , 'use_
json_null' , 'delete_key' , or 'return_target' . The default is 'use_json_null' .
jsonb_set_lax('[{"f1":1,"f2":null},2,null,3]', '{0,f1}', null)
→
[{"f1":null,"f2":null},2,null,3]

See also Section 9.21 for the aggregate function `json_agg` which aggregates record values as JSON, the aggregate function `json_object_agg` which aggregates pairs of values into a JSON object, and their `jsonb` equivalents, `jsonb_agg` and `jsonb_object_agg`.

### 9.16.2. The SQL/JSON Path Language

SQL/JSON path expressions specify the items to be retrieved from the JSON data, similar to XPath expressions used for SQL access to XML. In Postgres Pro, path expressions are implemented as the `jsonpath` data type and can use any elements described in Section 8.14.7.

JSON query functions and operators pass the provided path expression to the path engine for evaluation. If the expression matches the queried JSON data, the corresponding JSON item, or set of items, is returned. Path expressions are written in the SQL/JSON path language and can include arithmetic expressions and functions.

A path expression consists of a sequence of elements allowed by the `jsonpath` data type. The path expression is normally evaluated from left to right, but you can use parentheses to change the order of operations. If the evaluation is successful, a sequence of JSON items is produced, and the evaluation result is returned to the JSON query function that completes the specified computation.

To refer to the JSON value being queried (the context item), use the `$` variable in the path expression. It can be followed by one or more accessor operators, which go down the JSON structure level by level to retrieve sub-items of the context item. Each operator that follows deals with the result of the previous evaluation step.

For example, suppose you have some JSON data from a GPS tracker that you would like to parse, such as:

```json
{
    "track": {
        "segments": [
            {
                "location": [47.763, 13.4034],
                "start time": "2018-10-14 10:05:14",
                "HR": 73
            },
            {
                "location": [47.706, 13.2635],
                "start time": "2018-10-14 10:39:21",
                "HR": 135
            }
        ]
    }
}
```

To retrieve the available track segments, you need to use the `.key` accessor operator to descend through surrounding JSON objects:

```
$.track.segments
```

To retrieve the contents of an array, you typically use the `[*]` operator. For example, the following path will return the location coordinates for all the available track segments:

```
$.track.segments[*].location
```
To return the coordinates of the first segment only, you can specify the corresponding subscript in the `[]` accessor operator. Recall that JSON array indexes are 0-relative:

\[$.track.segments[0].location\]

The result of each path evaluation step can be processed by one or more `jsonpath` operators and methods listed in Section 9.16.2.2. Each method name must be preceded by a dot. For example, you can get the size of an array:

\[$.track.segments.size()\]

More examples of using `jsonpath` operators and methods within path expressions appear below in Section 9.16.2.2.

When defining a path, you can also use one or more filter expressions that work similarly to the `WHERE` clause in SQL. A filter expression begins with a question mark and provides a condition in parentheses:

\?[ (condition)\]

Filter expressions must be written just after the path evaluation step to which they should apply. The result of that step is filtered to include only those items that satisfy the provided condition. SQL/JSON defines three-valued logic, so the condition can be `true`, `false`, or `unknown`. The `unknown` value plays the same role as SQL `NULL` and can be tested for with the `is unknown` predicate. Further path evaluation steps use only those items for which the filter expression returned `true`.

The functions and operators that can be used in filter expressions are listed in Table 9.49. Within a filter expression, the `@` variable denotes the value being filtered (i.e., one result of the preceding path step). You can write accessor operators after `@` to retrieve component items.

For example, suppose you would like to retrieve all heart rate values higher than 130. You can achieve this using the following expression:

\[$.track.segments[*].HR ? (@ > 130)\]

To get the start times of segments with such values, you have to filter out irrelevant segments before returning the start times, so the filter expression is applied to the previous step, and the path used in the condition is different:

\[$.track.segments[*] ? (@.HR > 130)."start time"\]

You can use several filter expressions in sequence, if required. For example, the following expression selects start times of all segments that contain locations with relevant coordinates and high heart rate values:

\[$.track.segments[*] ? (@.location[1] < 13.4) ? (@.HR > 130)."start time"\]

Using filter expressions at different nesting levels is also allowed. The following example first filters all segments by location, and then returns high heart rate values for these segments, if available:

You can also nest filter expressions within each other:

\[$.track ? (exists(@.segments[*] ? (@.HR > 130))).segments.size()\]

This expression returns the size of the track if it contains any segments with high heart rate values, or an empty sequence otherwise.

Postgres Pro’s implementation of the SQL/JSON path language has the following deviations from the SQL/JSON standard:
Functions and Operators

- A path expression can be a Boolean predicate, although the SQL/JSON standard allows predicates only in filters. This is necessary for implementation of the @@ operator. For example, the following jsonpath expression is valid in Postgres Pro:
  \$\.track.segments\[\*\].HR < 70
- There are minor differences in the interpretation of regular expression patterns used in like_regex filters, as described in Section 9.16.2.3.

9.16.2.1. Strict and Lax Modes

When you query JSON data, the path expression may not match the actual JSON data structure. An attempt to access a non-existent member of an object or element of an array results in a structural error. SQL/JSON path expressions have two modes of handling structural errors:

- lax (default) — the path engine implicitly adapts the queried data to the specified path. Any remaining structural errors are suppressed and converted to empty SQL/JSON sequences.
- strict — if a structural error occurs, an error is raised.

The lax mode facilitates matching of a JSON document structure and path expression if the JSON data does not conform to the expected schema. If an operand does not match the requirements of a particular operation, it can be automatically wrapped as an SQL/JSON array or unwrapped by converting its elements into an SQL/JSON sequence before performing this operation. Besides, comparison operators automatically unwrap their operands in the lax mode, so you can compare SQL/JSON arrays out-of-the-box. An array of size 1 is considered equal to its sole element. Automatic unwrapping is not performed only when:

- The path expression contains type() or size() methods that return the type and the number of elements in the array, respectively.
- The queried JSON data contain nested arrays. In this case, only the outermost array is unwrapped, while all the inner arrays remain unchanged. Thus, implicit unwrapping can only go one level down within each path evaluation step.

For example, when querying the GPS data listed above, you can abstract from the fact that it stores an array of segments when using the lax mode:

lax \$\.track.segments\.location

In the strict mode, the specified path must exactly match the structure of the queried JSON document to return an SQL/JSON item, so using this path expression will cause an error. To get the same result as in the lax mode, you have to explicitly unwrap the segments array:

strict \$\.track.segments\[\*\].\.location

The .** accessor can lead to surprising results when using the lax mode. For instance, the following query selects every HR value twice:

lax \$.**.HR

This happens because the .** accessor selects both the segments array and each of its elements, while the .HR accessor automatically unwraps arrays when using the lax mode. To avoid surprising results, we recommend using the .** accessor only in the strict mode. The following query selects each HR value just once:

strict \$.**.HR

9.16.2.2. SQL/JSON Path Operators and Methods

Table 9.48 shows the operators and methods available in jsonpath. Note that while the unary operators and methods can be applied to multiple values resulting from a preceding path step, the binary operators (addition etc.) can only be applied to single values.
<table>
<thead>
<tr>
<th>Operator/Method</th>

| Date/time value converted from a string | jsonb_path_query('
  
  ["2015-8-1", "2015-08-12"]', 
  '$_[*] ? (\@.datetime() < "2015-08-2".datetime())')  
  → "2015-8-1" | |
| string . datetime( template ) → datetype_type | (see note) | |
| Date/time value converted from a string using the specified to_timestamp template | jsonb_path_query_array('
  
  ["12:30", "18:40"]', 
  '$[*].datetime("HH24:MI")') 
  → ["12:30:00", "18:40:00"] | |
| object . keyvalue() → array | The object's key-value pairs, represented as an array of objects containing three fields: "key", "value", and "id"; "id" is a unique identifier of the object the key-value pair belongs to | jsonb_path_query_array(
  
  "{x": "20", "y": 32}
  
  , "$ . keyvalue()"
  
  ) → [{"id": 0, "key": "x", "value": "20"}, {"id": 0, "key": "y", "value": 32}] |

### Note

The result type of the \( \text{datetime()} \) and \( \text{datetime(template)} \) methods can be date, timetz, time, timestamptz, or timestamp. Both methods determine their result type dynamically.

The \( \text{datetime()} \) method sequentially tries to match its input string to the ISO formats for date, timetz, time, timestamptz, and timestamp. It stops on the first matching format and emits the corresponding data type.

The \( \text{datetime(template)} \) method determines the result type according to the fields used in the provided template string.

The \( \text{datetime()} \) and \( \text{datetime(template)} \) methods use the same parsing rules as the \( \text{to_timestamp} \) SQL function does (see Section 9.8), with three exceptions. First, these methods don't allow unmatched template patterns. Second, only the following separators are allowed in the template string: minus sign, period, solidus (slash), comma, apostrophe, semicolon, colon and space. Third, separators in the template string must exactly match the input string.

If different date/time types need to be compared, an implicit cast is applied. A date value can be cast to timestamp or timestamptz, timestamp can be cast to timestamptz, and time to timetz. However, all but the first of these conversions depend on the current TimeZone setting, and thus can only be performed within timezone-aware jsonpath functions.

**Table 9.49** shows the available filter expression elements.

### Table 9.49. jsonpath Filter Expression Elements

<table>
<thead>
<tr>

<tr>
<td>boolean is unknown</td>
<td>boolean</td>
<td>Tests whether a Boolean condition is unknown. jsonb_path_query('[−1, 2, 7, &quot;foo&quot;], '$_' ? ((@ &gt; 0) is unknown)') → &quot;foo&quot;</td>
</tr>
</tbody>
</table>
### Functions and Operators

<table>
<thead>
<tr>
<th>Predicate/Value</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>string like_regex</strong></td>
<td>Tests whether the first operand matches the regular expression given by the second operand, optionally with modifications described by a string of flag characters (see Section 9.16.2.3).</td>
<td><code>jsonb_path_query_array([&quot;abc&quot;, &quot;abd&quot;, &quot;aBdC&quot;, &quot;abdacb&quot;, &quot;babc&quot;], '[$[*] ? (@ like_regex &quot;^ab.*c&quot;)]') → [&quot;abc&quot;, &quot;abd&quot;]</code></td>
</tr>
<tr>
<td></td>
<td></td>
<td><code>jsonb_path_query_array([&quot;abc&quot;, &quot;abd&quot;, &quot;aBdC&quot;, &quot;abdacb&quot;, &quot;babc&quot;], '[$[*] ? (@ like_regex &quot;^ab.*c&quot; flag &quot;i&quot;)]') → [&quot;abc&quot;, &quot;aBdC&quot;, &quot;abdacb&quot;]</code></td>
</tr>
</tbody>
</table>

**string starts with**

Tests whether the second operand is an initial substring of the first operand.

- `jsonb_path_query(['John Smith', 'Mary Stone', 'Bob Johnson'], '$[*] ? (@ starts with "John")') → "John Smith"`

**exists**

Tests whether a path expression matches at least one SQL/JSON item. Returns unknown if the path expression would result in an error; the second example uses this to avoid a no-such-key error in strict mode.

- `jsonb_path_query('{{"x": [1, 2], "y": [2, 4]}', 'strict $.? ? (exists (@ ? (@[*] > 2])))') → [2, 4]`
- `jsonb_path_query_array('{{"value": 41}', 'strict $ ? (exists (@.name)) .name') → []`

#### 9.16.2.3. SQL/JSON Regular Expressions

SQL/JSON path expressions allow matching text to a regular expression with the `like_regex` filter. For example, the following SQL/JSON path query would case-insensitively match all strings in an array that start with an English vowel:

```
$[*] ? (@ like_regex "^[aeiou]" flag "i")
```

The optional `flag` string may include one or more of the characters:

- `i` for case-insensitive match,
- `m` to allow `^` and `$` to match at newlines,
- `s` to allow `.` to match a newline, and
- `q` to quote the whole pattern (reducing the behavior to a simple substring match).

The SQL/JSON standard borrows its definition for regular expressions from the `LIKE_REGEX` operator, which in turn uses the XQuery standard. PostgreSQL does not currently support the `LIKE_REGEX` operator. Therefore, the `like_regex` filter is implemented using the POSIX regular expression engine described in Section 9.7.3. This leads to various minor discrepancies from standard SQL/JSON behavior, which are cataloged in Section 9.7.3.8. Note, however, that the flag-letter incompatibilities described there do not apply to SQL/JSON, as it translates the XQuery flag letters to match what the POSIX engine expects.

Keep in mind that the pattern argument of `like_regex` is a JSON path string literal, written according to the rules given in Section 8.14.7. This means in particular that any backslashes you want to use in the regular expression must be doubled. For example, to match string values of the root document that contain only digits:

```
$.? ? (@ like_regex "^\\d+$")
```

### 9.17. Sequence Manipulation Functions

This section describes functions for operating on **sequence objects**, also called sequence generators or just sequences. Sequence objects are special single-row tables created with `CREATE SEQUENCE`. Sequence objects are commonly used to generate unique identifiers for rows of a table. The sequence functions, listed in Table 9.50, provide simple, multiuser-safe methods for obtaining successive sequence values from sequence objects.
Functions and Operators

### Table 9.50. Sequence Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>nextval</strong> (regclass) → bigint</td>
<td>Advances the sequence object to its next value and returns that value. This is done atomically: even if multiple sessions execute <code>nextval</code> concurrently, each will safely receive a distinct sequence value. If the sequence object has been created with default parameters, successive <code>nextval</code> calls will return successive values beginning with 1. Other behaviors can be obtained by using appropriate parameters in the <code>CREATE SEQUENCE</code> command. This function requires <code>USAGE</code> or <code>UPDATE</code> privilege on the sequence.</td>
</tr>
<tr>
<td><strong>setval</strong> (regclass, bigint [, boolean ]) → bigint</td>
<td>Sets the sequence object’s current value, and optionally its <code>is-called</code> flag. The two-parameter form sets the sequence’s <code>last_value</code> field to the specified value and sets its <code>is-called</code> field to <code>true</code>, meaning that the next <code>nextval</code> will advance the sequence before returning a value. The value that will be reported by <code>currval</code> is also set to the specified value. In the three-parameter form, <code>is-called</code> can be set to either <code>true</code> or <code>false</code>. <code>true</code> has the same effect as the two-parameter form. If it is set to <code>false</code>, the next <code>nextval</code> will return exactly the specified value, and sequence advancement commences with the following <code>nextval</code>. Furthermore, the value reported by <code>currval</code> is not changed in this case. For example,</td>
</tr>
<tr>
<td><code>SELECT setval('myseq', 42);</code></td>
<td>Next <code>nextval</code> will return 43</td>
</tr>
<tr>
<td><code>SELECT setval('myseq', 42, true);</code></td>
<td>Same as above</td>
</tr>
<tr>
<td><code>SELECT setval('myseq', 42, false);</code></td>
<td>Next <code>nextval</code> will return 42</td>
</tr>
<tr>
<td><strong>currval</strong> (regclass) → bigint</td>
<td>Returns the value most recently obtained by <code>nextval</code> for this sequence in the current session. (An error is reported if <code>nextval</code> has never been called for this sequence in this session.) Because this is returning a session-local value, it gives a predictable answer whether or not other sessions have executed <code>nextval</code> since the current session did. This function requires <code>USAGE</code> or <code>SELECT</code> privilege on the sequence.</td>
</tr>
<tr>
<td><strong>lastval</strong> () → bigint</td>
<td>Returns the value most recently returned by <code>nextval</code> in the current session. This function is identical to <code>currval</code>, except that instead of taking the sequence name as an argument it refers to whichever sequence <code>nextval</code> was most recently applied to in the current session. It is an error to call <code>lastval</code> if <code>nextval</code> has not yet been called in the current session. This function requires <code>USAGE</code> or <code>SELECT</code> privilege on the last used sequence.</td>
</tr>
</tbody>
</table>

### Caution

To avoid blocking concurrent transactions that obtain numbers from the same sequence, a `nextval` operation is never rolled back; that is, once a value has been fetched it is considered used and will not be returned again. This is true even if the surrounding transaction later aborts, or if the calling query ends up not using the value. For example an `INSERT` with an `ON CONFLICT` clause will compute the to-be-inserted tuple, including doing any required `nextval` calls, before detecting any conflict that would cause it to follow the `ON CONFLICT` rule instead. Such cases will leave unused “holes” in the sequence of assigned values. Thus, Postgres Pro sequence objects cannot be used to obtain “gapless” sequences.

Likewise, any sequence state changes made by `setval` are not undone if the transaction rolls back.
The sequence to be operated on by a sequence function is specified by a regclass argument, which is simply the OID of the sequence in the pg_class system catalog. You do not have to look up the OID by hand, however, since the regclass data type's input converter will do the work for you. See Section 8.19 for details.

9.18. Conditional Expressions

This section describes the SQL-compliant conditional expressions available in Postgres Pro.

Tip

If your needs go beyond the capabilities of these conditional expressions, you might want to consider writing a server-side function in a more expressive programming language.

Note

Although COALESCE, GREATEST, and LEAST are syntactically similar to functions, they are not ordinary functions, and thus cannot be used with explicit VARIADIC array arguments.

9.18.1. CASE

The SQL CASE expression is a generic conditional expression, similar to if/else statements in other programming languages:

```
CASE WHEN condition THEN result
     [WHEN ...]
     [ELSE result]
END
```

CASE clauses can be used wherever an expression is valid. Each condition is an expression that returns a boolean result. If the condition's result is true, the value of the CASE expression is the result that follows the condition, and the remainder of the CASE expression is not processed. If the condition's result is not true, any subsequent WHEN clauses are examined in the same manner. If no WHEN condition yields true, the value of the CASE expression is the result of the ELSE clause. If the ELSE clause is omitted and no condition is true, the result is null.

An example:

```
SELECT * FROM test;
```

```
a ---
1
2
3
```

```
SELECT a,
     CASE WHEN a=1 THEN 'one'
          WHEN a=2 THEN 'two'
          ELSE 'other'
     END
FROM test;
```

```
a | case
---+------
1 | one
2 | two
```
The data types of all the result expressions must be convertible to a single output type. See Section 10.5 for more details.

There is a “simple” form of CASE expression that is a variant of the general form above:

```sql
CASE expression
  WHEN value THEN result
  [WHEN ...]
  [ELSE result]
END
```

The first expression is computed, then compared to each of the value expressions in the WHEN clauses until one is found that is equal to it. If no match is found, the result of the ELSE clause (or a null value) is returned. This is similar to the switch statement in C.

The example above can be written using the simple CASE syntax:

```sql
SELECT a,
  CASE a WHEN 1 THEN 'one'
          WHEN 2 THEN 'two'
          ELSE 'other'
  END
FROM test;
```

A CASE expression does not evaluate any subexpressions that are not needed to determine the result. For example, this is a possible way of avoiding a division-by-zero failure:

```sql
SELECT ... WHERE CASE WHEN x <> 0 THEN y/x > 1.5 ELSE false END;
```

### Note

As described in Section 4.2.14, there are various situations in which subexpressions of an expression are evaluated at different times, so that the principle that “CASE evaluates only necessary subexpressions” is not ironclad. For example a constant 1/0 subexpression will usually result in a division-by-zero failure at planning time, even if it's within a CASE arm that would never be entered at run time.

### 9.18.2. COALESCE

COALESCE(value [, ...])

The COALESCE function returns the first of its arguments that is not null. Null is returned only if all arguments are null. It is often used to substitute a default value for null values when data is retrieved for display, for example:

```sql
SELECT COALESCE(description, short_description, '(none)') ... 
```

This returns description if it is not null, otherwise short_description if it is not null, otherwise (none).

The arguments must all be convertible to a common data type, which will be the type of the result (see Section 10.5 for details).

Like a CASE expression, COALESCE only evaluates the arguments that are needed to determine the result; that is, arguments to the right of the first non-null argument are not evaluated. This SQL-standard function provides capabilities similar to NVL and IFNULL, which are used in some other database systems.
9.18.3. NULLIF

\[ \text{NULLIF}(\text{value1, value2}) \]

The `NULLIF` function returns a null value if `value1` equals `value2`; otherwise it returns `value1`. This can be used to perform the inverse operation of the `COALESCE` example given above:

```sql
SELECT NULLIF(value, '(none)') ...
```

In this example, if `value` is `(none)`, null is returned, otherwise the value of `value` is returned.

The two arguments must be of comparable types. To be specific, they are compared exactly as if you had written `value1 = value2`, so there must be a suitable `=` operator available.

The result has the same type as the first argument — but there is a subtlety. What is actually returned is the first argument of the implied `=` operator, and in some cases that will have been promoted to match the second argument's type. For example, `NULLIF(1, 2.2)` yields numeric, because there is no `integer = numeric` operator, only `numeric = numeric`.

9.18.4. GREATEST and LEAST

\[ \text{GREATEST}(\text{value }[, \ldots]) \]
\[ \text{LEAST}(\text{value }[, \ldots]) \]

The `GREATEST` and `LEAST` functions select the largest or smallest value from a list of any number of expressions. The expressions must all be convertible to a common data type, which will be the type of the result (see Section 10.5 for details). NULL values in the list are ignored. The result will be NULL only if all the expressions evaluate to NULL.

Note that `GREATEST` and `LEAST` are not in the SQL standard, but are a common extension. Some other databases make them return NULL if any argument is NULL, rather than only when all are NULL.

9.19. Array Functions and Operators

Table 9.51 shows the specialized operators available for array types. In addition to those, the usual comparison operators shown in Table 9.1 are available for arrays. The comparison operators compare the array contents element-by-element, using the default B-tree comparison function for the element data type, and sort based on the first difference. In multidimensional arrays the elements are visited in row-major order (last subscript varies most rapidly). If the contents of two arrays are equal but the dimensionality is different, the first difference in the dimensionality information determines the sort order.

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>anyarray @&gt; anyarray → boolean</td>
<td>Does the first array contain the second, that is, does each element appearing in the second array equal some element of the first array? (Duplicates are not treated specially, thus <code>ARRAY[1] and ARRAY[1,1]</code> are each considered to contain the other.)</td>
<td><code>ARRAY[1,4,3] @&gt; ARRAY[3,1,3] → t</code></td>
</tr>
<tr>
<td>anyarray &lt;@ anyarray → boolean</td>
<td>Is the first array contained by the second?</td>
<td><code>ARRAY[2,2,7] &lt;@ ARRAY[1,7,4,2,6] → t</code></td>
</tr>
<tr>
<td>anyarray &amp;&amp; anyarray → boolean</td>
<td>Do the arrays overlap, that is, have any elements in common?</td>
<td><code>ARRAY[1,4,3] &amp;&amp; ARRAY[2,1] → t</code></td>
</tr>
<tr>
<td>anycompatiblearray</td>
<td></td>
<td>anycompatiblearray → anycompatiblearray</td>
</tr>
</tbody>
</table>
Functions and Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Concatenates the two arrays. Concatenating a null or empty array is a no-op; otherwise the arrays must have the same number of dimensions (as illustrated by the first example) or differ in number of dimensions by one (as illustrated by the second). If the arrays are not of identical element types, they will be coerced to a common type (see Section 10.5).</td>
<td></td>
<td></td>
</tr>
<tr>
<td>ARRAY[1,2,3]</td>
<td></td>
<td>ARRAY[4,5,6,7] → {1,2,3,4,5,6,7}</td>
</tr>
<tr>
<td>ARRAY[1,2,3]</td>
<td></td>
<td>ARRAY[[4,5,6],[7,8,9.9]] → {{1,2,3},{4,5,6},{7,8,9.9}}</td>
</tr>
<tr>

<tbody>
<tr>
<td>array_lower</td>
<td>Returns the first occurrence of the second argument in the array, or NULL if it's not present. If the third argument is given, the search begins at that subscript. The array must be one-dimensional. Comparisons are done using IS NOT DISTINCT FROM semantics, so it is possible to search for NULL.</td>
<td>array_lower('sun', 'mon', 'tue', 'wed', 'thu', 'fri', 'sat'), 'mon') (\rightarrow) 2</td>
</tr>
<tr>
<td>array_upper</td>
<td>Returns the upper bound of the requested array dimension.</td>
<td>array_upper(ARRAY[1,8,3,7], 1) (\rightarrow) 4</td>
</tr>
<tr>
<td>cardinality</td>
<td>Returns the total number of elements in the array, or 0 if the array is empty.</td>
<td>cardinality(ARRAY[[1,2],[3,4]]) (\rightarrow) 4</td>
</tr>
<tr>
<td>trim_array</td>
<td>Trims an array by removing the last (n) elements. If the array is multidimensional, only the first dimension is trimmed.</td>
<td>trim_array(ARRAY[1,2,3,4,5,6], 2) (\rightarrow) {1,2,3,4}</td>
</tr>
</tbody>
</table>
### Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
</table>
| **unnest** (anyarray) → setof anyelement | Expands an array into a set of rows. The array's elements are read out in storage order. | unnest (ARRAY[1,2]) → 1 2  
unnest (ARRAY[['foo','bar'],['baz','quux']]) → foo bar baz quux |

| unnest (anyarray, anyarray [,...]) → setof anyelement, anyelement [,...] | Expands multiple arrays (possibly of different data types) into a set of rows. If the arrays are not all the same length then the shorter ones are padded with NULLs. This form is only allowed in a query's FROM clause; see Section 7.2.1.4. | select * from unnest(ARRAY[1,2], ARRAY['foo','bar','baz']) as x(a,b) → a | b  
1 | foo  
2 | bar  
   | baz |

#### Note

There are two differences in the behavior of `string_to_array` from pre-9.1 versions of PostgreSQL. First, it will return an empty (zero-element) array rather than NULL when the input string is of zero length. Second, if the delimiter string is NULL, the function splits the input into individual characters, rather than returning NULL as before.

See also Section 9.21 about the aggregate function `array_agg` for use with arrays.

### 9.20. Range/Multirange Functions and Operators

See Section 8.17 for an overview of range types.

Table 9.53 shows the specialized operators available for range types. Table 9.54 shows the specialized operators available for multirange types. In addition to those, the usual comparison operators shown in Table 9.1 are available for range and multirange types. The comparison operators order first by the range lower bounds, and only if those are equal do they compare the upper bounds. The multirange operators compare each range until one is unequal. This does not usually result in a useful overall ordering, but the operators are provided to allow unique indexes to be constructed on ranges.

<td></td>
</tr>
</tbody>
</table>

297
The left-of/right-of/adjacent operators always return false when an empty range or multirange is involved; that is, an empty range is not considered to be either before or after any other range.

Elsewhere empty ranges and multiranges are treated as the additive identity: anything unioned with an empty value is itself. Anything minus an empty value is itself. An empty multirange has exactly the same points as an empty range. Every range contains the empty range. Every multirange contains as many empty ranges as you like.

The range union and difference operators will fail if the resulting range would need to contain two disjoint sub-ranges, as such a range cannot be represented. There are separate operators for union and difference that take multirange parameters and return a multirange, and they do not fail even if their arguments are disjoint. So if you need a union or difference operation for ranges that may be disjoint, you can avoid errors by first casting your ranges to multiranges.

Table 9.55 shows the functions available for use with range types. Table 9.56 shows the functions available for use with multirange types.

<td>range_merge('[(1,2), (3,4)]'::int4multirange) → [1,4)</td>
</tr>
<tr>
<td>multirange (anyrange) → anymultirange</td>
<td>Returns a multirange containing just the given range.</td>
<td>multirange('[1,2]'::int4range) → {[1,2]}</td>
</tr>
<tr>
<td>unnest (anymultirange) → setof anyrange</td>
<td>Expands a multirange into a set of ranges. The ranges are read out in storage order (ascending).</td>
<td>unnest('[(1,2), (3,4)]'::int4multirange) → {[1,2), [3,4)}</td>
</tr>
</tbody>
</table>
The `lower_inc`, `upper_inc`, `lower_inf`, and `upper_inf` functions all return false for an empty range or multirange.

## 9.21. Aggregate Functions

*Aggregate functions* compute a single result from a set of input values. The built-in general-purpose aggregate functions are listed in Table 9.57 while statistical aggregates are in Table 9.58. The built-in within-group ordered-set aggregate functions are listed in Table 9.59 while the built-in within-group hypothetical-set ones are in Table 9.60. Grouping operations, which are closely related to aggregate functions, are listed in Table 9.61. The special syntax considerations for aggregate functions are explained in Section 4.2.7. Consult Section 2.7 for additional introductory information.

Aggregate functions that support *Partial Mode* are eligible to participate in various optimizations, such as parallel aggregation.

### Table 9.57. General-Purpose Aggregate Functions

<table>

</tr>
<tr>
<td>sum(money)</td>
<td>(money) → money</td>
<td>Yes</td>
</tr>
<tr>
<td>xmlagg</td>
<td>(xml) → xml</td>
<td>No</td>
</tr>
</tbody>
</table>

*Note: For the 'sum' function, the type of the non-null input values determines the output type.*
It should be noted that except for `count`, these functions return a null value when no rows are selected. In particular, `sum` of no rows returns null, not zero as one might expect, and `array_agg` returns null rather than an empty array when there are no input rows. The `coalesce` function can be used to substitute zero or an empty array for null when necessary.

The aggregate functions `array_agg`, `json_agg`, `jsonb_agg`, `json_object_agg`, `jsonb_object_agg`, `string_agg`, and `xmlagg`, as well as similar user-defined aggregate functions, produce meaningfully different result values depending on the order of the input values. This ordering is unspecified by default, but can be controlled by writing an `ORDER BY` clause within the aggregate call, as shown in Section 4.2.7. Alternatively, supplying the input values from a sorted subquery will usually work. For example:

```sql
SELECT xmlagg(x) FROM (SELECT x FROM test ORDER BY y DESC) AS tab;
```

Beware that this approach can fail if the outer query level contains additional processing, such as a join, because that might cause the subquery's output to be reordered before the aggregate is computed.

**Note**

The boolean aggregates `bool_and` and `bool_or` correspond to the standard SQL aggregates `every` and `any` or `some`. PostgreSQL supports `every`, but not `any` or `some`, because there is an ambiguity built into the standard syntax:

```sql
SELECT b1 = ANY((SELECT b2 FROM t2 ...)) FROM t1 ...;
```

Here `ANY` can be considered either as introducing a subquery, or as being an aggregate function, if the subquery returns one row with a Boolean value. Thus the standard name cannot be given to these aggregates.

**Note**

Users accustomed to working with other SQL database management systems might be disappointed by the performance of the `count` aggregate when it is applied to the entire table. A query like:

```sql
SELECT count(*) FROM sometable;
```

will require effort proportional to the size of the table: Postgres Pro will need to scan either the entire table or the entirety of an index that includes all rows in the table.

Table 9.58 shows aggregate functions typically used in statistical analysis. (These are separated out merely to avoid cluttering the listing of more-commonly-used aggregates.) Functions shown as accepting `numeric_type` are available for all the types `smallint`, `integer`, `bigint`, `numeric`, `real`, and `double precision`. Where the description mentions `N`, it means the number of input rows for which all the input expressions are non-null. In all cases, null is returned if the computation is meaningless, for example when `N` is zero.

<td>Yes</td>
</tr>
<tr>
<td><strong>regr_syy</strong></td>
<td>Computes the “sum of squares” of the dependent variable, ( \sum Y^2 - \frac{\sum Y^2}{N} ).</td>
<td>Yes</td>
</tr>
<tr>
<td><strong>stddev</strong></td>
<td>Computes the population standard deviation of the input values.</td>
<td>Yes</td>
</tr>
<tr>
<td><strong>stddev_pop</strong></td>
<td>Computes the sample standard deviation of the input values.</td>
<td>Yes</td>
</tr>
<tr>
<td><strong>stddev_samp</strong></td>
<td>Computes the sample standard deviation of the input values.</td>
<td>Yes</td>
</tr>
<tr>
<td><strong>variance</strong></td>
<td>Computes the population variance of the input values (square of the population standard deviation).</td>
<td>Yes</td>
</tr>
<tr>
<td><strong>var_pop</strong></td>
<td>Computes the sample variance of the input values (square of the sample standard deviation).</td>
<td>Yes</td>
</tr>
</tbody>
</table>

Table 9.59 shows some aggregate functions that use the ordered-set aggregate syntax. These functions are sometimes referred to as “inverse distribution” functions. Their aggregated input is introduced by ORDER BY, and they may also take a direct argument that is not aggregated, but is computed only once. All
Functions and Operators

these functions ignore null values in their aggregated input. For those that take a `fraction` parameter, the fraction value must be between 0 and 1; an error is thrown if not. However, a null `fraction` value simply produces a null result.

Table 9.59. Ordered-Set Aggregate Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Partial Mode</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>mode()</code> WITHIN GROUP (ORDER BY anyelement) → anyelement</td>
<td>Computes the mode, the most frequent value of the aggregated argument (arbitrarily choosing the first one if there are multiple equally-frequent values). The aggregated argument must be of a sortable type.</td>
<td>No</td>
</tr>
<tr>
<td><code>percentile_cont (fraction double precision) WITHIN GROUP (ORDER BY double precision) → double precision</code></td>
<td>Computes the continuous percentile, a value corresponding to the specified <code>fraction</code> within the ordered set of aggregated argument values. This will interpolate between adjacent input items if needed.</td>
<td>No</td>
</tr>
<tr>
<td><code>percentile_cont (fractions double precision[]) WITHIN GROUP (ORDER BY double precision[]) → double precision[]</code></td>
<td>Computes multiple continuous percentiles. The result is an array of the same dimensions as the <code>fractions</code> parameter, with each non-null element replaced by the (possibly interpolated) value corresponding to that percentile.</td>
<td>No</td>
</tr>
<tr>
<td><code>percentile_disc (fraction double precision) WITHIN GROUP (ORDER BY anyelement) → anyelement</code></td>
<td>Computes the discrete percentile, the first value within the ordered set of aggregated argument values whose position in the ordering equals or exceeds the specified <code>fraction</code>. The aggregated argument must be of a sortable type.</td>
<td>No</td>
</tr>
<tr>
<td><code>percentile_disc (fractions double precision[]) WITHIN GROUP (ORDER BY anyelement) → anyarray</code></td>
<td>Computes multiple discrete percentiles. The result is an array of the same dimensions as the <code>fractions</code> parameter, with each non-null element replaced by the input value corresponding to that percentile. The aggregated argument must be of a sortable type.</td>
<td>No</td>
</tr>
</tbody>
</table>

Each of the “hypothetical-set” aggregates listed in Table 9.60 is associated with a window function of the same name defined in Section 9.22. In each case, the aggregate’s result is the value that the associated window function would have returned for the “hypothetical” row constructed from `args`, if such a row had been added to the sorted group of rows represented by the `sorted_args`. For each of these functions, the list of direct arguments given in `args` must match the number and types of the aggregated arguments given in `sorted_args`. Unlike most built-in aggregates, these aggregates are not strict, that is they do not drop input rows containing nulls. Null values sort according to the rule specified in the `ORDER BY` clause.

Table 9.60. Hypothetical-Set Aggregate Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Partial Mode</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>rank (args) WITHIN GROUP (ORDER BY sorted_args) → bigint</code></td>
<td>Computes the rank of the hypothetical row, with gaps; that is, the row number of the first row in its peer group.</td>
<td>No</td>
</tr>
</tbody>
</table>
### Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Partial Mode</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>dense_rank</strong> ((args)) WITHIN GROUP (ORDER BY sorted_args) (\rightarrow) bigint</td>
<td>Computes the rank of the hypothetical row, without gaps; this function effectively counts peer groups.</td>
<td>No</td>
</tr>
<tr>
<td><strong>percent_rank</strong> ((args)) WITHIN GROUP (ORDER BY sorted_args) (\rightarrow) double precision</td>
<td>Computes the relative rank of the hypothetical row, that is ((\text{rank} - 1) / (\text{total rows} - 1)). The value thus ranges from 0 to 1 inclusive.</td>
<td>No</td>
</tr>
<tr>
<td><strong>cume_dist</strong> ((args)) WITHIN GROUP (ORDER BY sorted_args) (\rightarrow) double precision</td>
<td>Computes the cumulative distribution, that is ((\text{number of rows preceding or peers with hypothetical row}) / (\text{total rows})). The value thus ranges from (1/N) to 1.</td>
<td>No</td>
</tr>
</tbody>
</table>

#### Table 9.61. Grouping Operations

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>GROUPING</strong> ((\text{group_by_expression(s)})) (\rightarrow) integer</td>
<td>Returns a bit mask indicating which \text{GROUP BY} expressions are not included in the current grouping set. Bits are assigned with the rightmost argument corresponding to the least-significant bit; each bit is 0 if the corresponding expression is included in the grouping criteria of the grouping set generating the current result row, and 1 if it is not included.</td>
</tr>
</tbody>
</table>

The grouping operations shown in Table 9.61 are used in conjunction with grouping sets (see Section 7.2.4) to distinguish result rows. The arguments to the **GROUPING** function are not actually evaluated, but they must exactly match expressions given in the \text{GROUP BY} clause of the associated query level. For example:

\[
\text{=> SELECT * FROM items_sold;}
\]

<table>
<thead>
<tr>
<th>make</th>
<th>model</th>
<th>sales</th>
</tr>
</thead>
<tbody>
<tr>
<td>Foo</td>
<td>GT</td>
<td>10</td>
</tr>
<tr>
<td>Foo</td>
<td>Tour</td>
<td>20</td>
</tr>
<tr>
<td>Bar</td>
<td>City</td>
<td>15</td>
</tr>
<tr>
<td>Bar</td>
<td>Sport</td>
<td>5</td>
</tr>
</tbody>
</table>

\(4\) rows

\[
\text{=> SELECT make, model, GROUPING(make,model), sum(sales) FROM items_sold GROUP BY ROLLUP(make,model);}\
\]

<table>
<thead>
<tr>
<th>make</th>
<th>model</th>
<th>grouping</th>
<th>sum</th>
</tr>
</thead>
<tbody>
<tr>
<td>Foo</td>
<td>GT</td>
<td>0</td>
<td>10</td>
</tr>
<tr>
<td>Foo</td>
<td>Tour</td>
<td>0</td>
<td>20</td>
</tr>
<tr>
<td>Bar</td>
<td>City</td>
<td>0</td>
<td>15</td>
</tr>
<tr>
<td>Bar</td>
<td>Sport</td>
<td>0</td>
<td>5</td>
</tr>
<tr>
<td>Foo</td>
<td></td>
<td>1</td>
<td>30</td>
</tr>
<tr>
<td>Bar</td>
<td></td>
<td>1</td>
<td>20</td>
</tr>
<tr>
<td></td>
<td></td>
<td>3</td>
<td>50</td>
</tr>
</tbody>
</table>

\(7\) rows

Here, the grouping value 0 in the first four rows shows that those have been grouped normally, over both the grouping columns. The value 1 indicates that model was not grouped by in the next-to-last two rows, and the value 3 indicates that neither make nor model was grouped by in the last row (which therefore is an aggregate over all the input rows).

### 9.22. Window Functions

Window functions provide the ability to perform calculations across sets of rows that are related to the current query row. See Section 3.5 for an introduction to this feature, and Section 4.2.8 for syntax details.
The built-in window functions are listed in Table 9.62. Note that these functions must be invoked using window function syntax, i.e., an OVER clause is required.

In addition to these functions, any built-in or user-defined ordinary aggregate (i.e., not ordered-set or hypothetical-set aggregates) can be used as a window function; see Section 9.21 for a list of the built-in aggregates. Aggregate functions act as window functions only when an OVER clause follows the call; otherwise they act as plain aggregates and return a single row for the entire set.

Table 9.62. General-Purpose Window Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>row_number () (\rightarrow) bigint</td>
<td>Returns the number of the current row within its partition, counting from 1.</td>
</tr>
<tr>
<td>rank () (\rightarrow) bigint</td>
<td>Returns the rank of the current row, with gaps; that is, the row_number of the first row in its peer group.</td>
</tr>
<tr>
<td>dense_rank () (\rightarrow) bigint</td>
<td>Returns the rank of the current row, without gaps; this function effectively counts peer groups.</td>
</tr>
<tr>
<td>percent_rank () (\rightarrow) double precision</td>
<td>Returns the relative rank of the current row, that is ((\text{rank} - 1) / (\text{total partition rows} - 1)). The value thus ranges from 0 to 1 inclusive.</td>
</tr>
<tr>
<td>cume_dist () (\rightarrow) double precision</td>
<td>Returns the cumulative distribution, that is ((\text{number of partition rows preceding or peers with current row}) / (\text{total partition rows})). The value thus ranges from (1/N) to 1.</td>
</tr>
<tr>
<td>ntile (num_buckets integer) (\rightarrow) integer</td>
<td>Returns an integer ranging from 1 to the argument value, dividing the partition as equally as possible.</td>
</tr>
<tr>
<td>lag (value anycompatible [ , offset integer [ , default anycompatible ]] ) (\rightarrow) anycompatible</td>
<td>Returns value evaluated at the row that is offset rows before the current row within the partition; if there is no such row, instead returns default (which must be of a type compatible with value). Both offset and default are evaluated with respect to the current row. If omitted, offset defaults to 1 and default to NULL.</td>
</tr>
<tr>
<td>lead (value anycompatible [ , offset integer [ , default anycompatible ]] ) (\rightarrow) anycompatible</td>
<td>Returns value evaluated at the row that is offset rows after the current row within the partition; if there is no such row, instead returns default (which must be of a type compatible with value). Both offset and default are evaluated with respect to the current row. If omitted, offset defaults to 1 and default to NULL.</td>
</tr>
<tr>
<td>first_value (value anyelement) (\rightarrow) anyelement</td>
<td>Returns value evaluated at the row that is the first row of the window frame.</td>
</tr>
<tr>
<td>last_value (value anyelement) (\rightarrow) anyelement</td>
<td>Returns value evaluated at the row that is the last row of the window frame.</td>
</tr>
<tr>
<td>nth_value (value anyelement, n integer) (\rightarrow) anyelement</td>
<td>Returns value evaluated at the row that is the n'th row of the window frame (counting from 1); returns NULL if there is no such row.</td>
</tr>
</tbody>
</table>

All of the functions listed in Table 9.62 depend on the sort ordering specified by the ORDER BY clause of the associated window definition. Rows that are not distinct when considering only the ORDER BY columns are said to be peers. The four ranking functions (including cume_dist) are defined so that they give the same answer for all rows of a peer group.
Note that first_value, last_value, and nth_value consider only the rows within the “window frame”, which by default contains the rows from the start of the partition through the last peer of the current row. This is likely to give unhelpful results for last_value and sometimes also nth_value. You can redefine the frame by adding a suitable frame specification (RANGE, ROWS or GROUPS) to the OVER clause. See Section 4.2.8 for more information about frame specifications.

When an aggregate function is used as a window function, it aggregates over the rows within the current row's window frame. An aggregate used with ORDER BY and the default window frame definition produces a “running sum” type of behavior, which may or may not be what’s wanted. To obtain aggregation over the whole partition, omit ORDER BY or use ROWS BETWEEN UNBOUNDED PRECEDING AND UNBOUNDED FOLLOWING. Other frame specifications can be used to obtain other effects.

Note

The SQL standard defines a RESPECT NULLS or IGNORE NULLS option for lead, lag, first_value, last_value, and nth_value. This is not implemented in Postgres Pro: the behavior is always the same as the standard's default, namely RESPECT NULLS. Likewise, the standard's FROM FIRST or FROM LAST option for nth_value is not implemented: only the default FROM FIRST behavior is supported. (You can achieve the result of FROM LAST by reversing the ORDER BY ordering.)

9.23. Subquery Expressions

This section describes the SQL-compliant subquery expressions available in Postgres Pro. All of the expression forms documented in this section return Boolean (true/false) results.

9.23.1. EXISTS

EXISTS (subquery)

The argument of EXISTS is an arbitrary SELECT statement, or subquery. The subquery is evaluated to determine whether it returns any rows. If it returns at least one row, the result of EXISTS is “true”; if the subquery returns no rows, the result of EXISTS is “false”.

The subquery can refer to variables from the surrounding query, which will act as constants during any one evaluation of the subquery.

The subquery will generally only be executed long enough to determine whether at least one row is returned, not all the way to completion. It is unwise to write a subquery that has side effects (such as calling sequence functions); whether the side effects occur might be unpredictable.

Since the result depends only on whether any rows are returned, and not on the contents of those rows, the output list of the subquery is normally unimportant. A common coding convention is to write all EXISTS tests in the form EXISTS (SELECT 1 WHERE ...). There are exceptions to this rule however, such as subqueries that use INTERSECT.

This simple example is like an inner join on col2, but it produces at most one output row for each tab1 row, even if there are several matching tab2 rows:

```
SELECT col1
FROM tab1
WHERE EXISTS (SELECT 1 FROM tab2 WHERE col2 = tab1.col2);
```

9.23.2. IN

expression IN (subquery)

The right-hand side is a parenthesized subquery, which must return exactly one column. The left-hand expression is evaluated and compared to each row of the subquery result. The result of IN is “true” if any equal subquery row is found. The result is “false” if no equal row is found (including the case where the subquery returns no rows).
Note that if the left-hand expression yields null, or if there are no equal right-hand values and at least one right-hand row yields null, the result of the \texttt{IN} construct will be null, not false. This is in accordance with SQL's normal rules for Boolean combinations of null values.

As with \texttt{EXISTS}, it's unwise to assume that the subquery will be evaluated completely.

\texttt{row_constructor IN (subquery)}

The left-hand side of this form of \texttt{IN} is a row constructor, as described in Section 4.2.13. The right-hand side is a parenthesized subquery, which must return exactly as many columns as there are expressions in the left-hand row. The left-hand expressions are evaluated and compared row-wise to each row of the subquery result. The result of \texttt{IN} is “true” if any equal subquery row is found. The result is “false” if no equal row is found (including the case where the subquery returns no rows).

As usual, null values in the rows are combined per the normal rules of SQL Boolean expressions. Two rows are considered equal if all their corresponding members are non-null and equal; the rows are unequal if any corresponding members are non-null and unequal; otherwise the result of that row comparison is unknown (null). If all the per-row results are either unequal or null, with at least one null, then the result of \texttt{IN} is null.

\subsection{9.23.3. NOT IN}

\texttt{expression NOT IN (subquery)}

The right-hand side is a parenthesized subquery, which must return exactly one column. The left-hand expression is evaluated and compared to each row of the subquery result. The result of \texttt{NOT IN} is “true” if only unequal subquery rows are found (including the case where the subquery returns no rows). The result is “false” if any equal row is found.

Note that if the left-hand expression yields null, or if there are no equal right-hand values and at least one right-hand row yields null, the result of the \texttt{NOT IN} construct will be null, not true. This is in accordance with SQL's normal rules for Boolean combinations of null values.

As with \texttt{EXISTS}, it's unwise to assume that the subquery will be evaluated completely.

\texttt{row_constructor NOT IN (subquery)}

The left-hand side of this form of \texttt{NOT IN} is a row constructor, as described in Section 4.2.13. The right-hand side is a parenthesized subquery, which must return exactly as many columns as there are expressions in the left-hand row. The left-hand expressions are evaluated and compared row-wise to each row of the subquery result. The result of \texttt{NOT IN} is “true” if only unequal subquery rows are found (including the case where the subquery returns no rows). The result is “false” if any equal row is found.

As usual, null values in the rows are combined per the normal rules of SQL Boolean expressions. Two rows are considered equal if all their corresponding members are non-null and equal; the rows are unequal if any corresponding members are non-null and unequal; otherwise the result of that row comparison is unknown (null). If all the per-row results are either unequal or null, with at least one null, then the result of \texttt{NOT IN} is null.

\subsection{9.23.4. ANY/SOME}

\texttt{expression operator ANY (subquery)}
\texttt{expression operator SOME (subquery)}

The right-hand side is a parenthesized subquery, which must return exactly one column. The left-hand expression is evaluated and compared to each row of the subquery result using the given \texttt{operator}, which must yield a Boolean result. The result of \texttt{ANY} is “true” if any true result is obtained. The result is “false” if no true result is found (including the case where the subquery returns no rows).

SOME is a synonym for \texttt{ANY}. \texttt{IN} is equivalent to \texttt{= ANY}.

Note that if there are no successes and at least one right-hand row yields null for the operator's result, the result of the \texttt{ANY} construct will be null, not false. This is in accordance with SQL's normal rules for Boolean combinations of null values.
As with EXISTs, it's unwise to assume that the subquery will be evaluated completely.

```
row_constructor operator ANY (subquery)
row_constructor operator SOME (subquery)
```

The left-hand side of this form of ANY is a row constructor, as described in Section 4.2.13. The right-hand side is a parenthesized subquery, which must return exactly as many columns as there are expressions in the left-hand row. The left-hand expressions are evaluated and compared row-wise to each row of the subquery result, using the given operator. The result of ANY is "true" if the comparison returns true for any subquery row. The result is "false" if the comparison returns false for every subquery row (including the case where the subquery returns no rows). The result is NULL if no comparison with a subquery row returns true, and at least one comparison returns NULL.

See Section 9.24.5 for details about the meaning of a row constructor comparison.

9.23.5. ALL

```
expression operator ALL (subquery)
```

The right-hand side is a parenthesized subquery, which must return exactly one column. The left-hand expression is evaluated and compared to each row of the subquery result using the given operator, which must yield a Boolean result. The result of ALL is "true" if all rows yield true (including the case where the subquery returns no rows). The result is "false" if any false result is found. The result is NULL if no comparison with a subquery row returns false, and at least one comparison returns NULL.

NOT IN is equivalent to <> ALL.

As with EXISTs, it's unwise to assume that the subquery will be evaluated completely.

```
row_constructor operator ALL (subquery)
```

The left-hand side of this form of ALL is a row constructor, as described in Section 4.2.13. The right-hand side is a parenthesized subquery, which must return exactly as many columns as there are expressions in the left-hand row. The left-hand expressions are evaluated and compared row-wise to each row of the subquery result, using the given operator. The result of ALL is "true" if the comparison returns true for all subquery rows (including the case where the subquery returns no rows). The result is "false" if the comparison returns false for any subquery row. The result is NULL if no comparison with a subquery row returns false, and at least one comparison returns NULL.

See Section 9.24.5 for details about the meaning of a row constructor comparison.

9.23.6. Single-Row Comparison

```
row_constructor operator (subquery)
```

The left-hand side is a row constructor, as described in Section 4.2.13. The right-hand side is a parenthesized subquery, which must return exactly as many columns as there are expressions in the left-hand row. Furthermore, the subquery cannot return more than one row. (If it returns zero rows, the result is taken to be null.) The left-hand side is evaluated and compared row-wise to the single subquery result row.

See Section 9.24.5 for details about the meaning of a row constructor comparison.

9.24. Row and Array Comparisons

This section describes several specialized constructs for making multiple comparisons between groups of values. These forms are syntactically related to the subquery forms of the previous section, but do not involve subqueries. The forms involving array subexpressions are Postgres Pro extensions; the rest are SQL-compliant. All of the expression forms documented in this section return Boolean (true/false) results.

9.24.1. IN

```
expression IN (value [, ...])
```

The right-hand side is a parenthesized list of scalar expressions. The result is “true” if the left-hand expression's result is equal to any of the right-hand expressions. This is a shorthand notation for

```
ext = value1
OR
expression = value2
OR
...
```

Note that if the left-hand expression yields null, or if there are no equal right-hand values and at least one right-hand expression yields null, the result of the `IN` construct will be null, not false. This is in accordance with SQL's normal rules for Boolean combinations of null values.

### 9.24.2. NOT IN

```
ext NOT IN (value [, ...])
```

The right-hand side is a parenthesized list of scalar expressions. The result is “true” if the left-hand expression's result is unequal to all of the right-hand expressions. This is a shorthand notation for

```
ext <> value1
AND
expression <> value2
AND
...
```

Note that if the left-hand expression yields null, or if there are no equal right-hand values and at least one right-hand expression yields null, the result of the `NOT IN` construct will be null, not true as one might naively expect. This is in accordance with SQL's normal rules for Boolean combinations of null values.

**Tip**

```
x NOT IN y is equivalent to NOT (x IN y) in all cases. However, null values are much more likely to trip up the novice when working with NOT IN than when working with IN. It is best to express your condition positively if possible.
```

### 9.24.3. ANY/SOME (array)

```
ext operator ANY (array expression)
ext operator SOME (array expression)
```

The right-hand side is a parenthesized expression, which must yield an array value. The left-hand expression is evaluated and compared to each element of the array using the given `operator`, which must yield a Boolean result. The result of `ANY` is “true” if any true result is obtained. The result is “false” if no true result is found (including the case where the array has zero elements).

If the array expression yields a null array, the result of `ANY` will be null. If the left-hand expression yields null, the result of `ANY` is ordinarily null (though a non-strict comparison operator could possibly yield a different result). Also, if the right-hand array contains any null elements and no true comparison result is obtained, the result of `ANY` will be null, not false (again, assuming a strict comparison operator). This is in accordance with SQL's normal rules for Boolean combinations of null values.

`SOME` is a synonym for `ANY`.

### 9.24.4. ALL (array)

```
ext operator ALL (array expression)
```

The right-hand side is a parenthesized expression, which must yield an array value. The left-hand expression is evaluated and compared to each element of the array using the given `operator`, which must yield a Boolean result. The result of `ALL` is “true” if all comparisons yield true (including the case where the array has zero elements). The result is “false” if any false result is found.
If the array expression yields a null array, the result of \texttt{ALL} will be null. If the left-hand expression yields null, the result of \texttt{ALL} is ordinarily null (though a non-strict comparison operator could possibly yield a different result). Also, if the right-hand array contains any null elements and no false comparison result is obtained, the result of \texttt{ALL} will be null, not true (again, assuming a strict comparison operator). This is in accordance with SQL’s normal rules for Boolean combinations of null values.

### 9.24.5. Row Constructor Comparison

\texttt{row\_constructor \ operator \ row\_constructor}

Each side is a row constructor, as described in Section 4.2.13. The two row values must have the same number of fields. Each side is evaluated and they are compared row-wise. Row constructor comparisons are allowed when the \texttt{operator} is \texttt{=}, \texttt{<>}, \texttt{<}, \texttt{<=}, \texttt{>} or \texttt{>=}. Every row element must be of a type which has a default B-tree operator class or the attempted comparison may generate an error.

\begin{Verbatim}
Note

Errors related to the number or types of elements might not occur if the comparison is resolved using earlier columns.
\end{Verbatim}

The \texttt{=} and \texttt{<>} cases work slightly differently from the others. Two rows are considered equal if all their corresponding members are non-null and equal; the rows are unequal if any corresponding members are non-null and unequal; otherwise the result of the row comparison is unknown (null).

For the \texttt{<}, \texttt{<=}, \texttt{>} and \texttt{>=} cases, the row elements are compared left-to-right, stopping as soon as an unequal or null pair of elements is found. If either of this pair of elements is null, the result of the row comparison is unknown (null); otherwise comparison of this pair of elements determines the result. For example, \texttt{ROW(1,2,NULL) < ROW(1,3,0)} yields true, not null, because the third pair of elements are not considered.

\begin{Verbatim}
Note

Prior to PostgreSQL 8.2, the \texttt{<}, \texttt{<=}, \texttt{>} and \texttt{>=} cases were not handled per SQL specification. A comparison like \texttt{ROW(a,b) < ROW(c,d)} was implemented as \texttt{a < c AND b < d} whereas the correct behavior is equivalent to \texttt{a < c OR (a = c AND b < d)}.
\end{Verbatim}

\texttt{row\_constructor IS DISTINCT FROM row\_constructor}

This construct is similar to a \texttt{<>} row comparison, but it does not yield null for null inputs. Instead, any null value is considered unequal to (distinct from) any non-null value, and any two nulls are considered equal (not distinct). Thus the result will either be true or false, never null.

\texttt{row\_constructor IS NOT DISTINCT FROM row\_constructor}

This construct is similar to a \texttt{=} row comparison, but it does not yield null for null inputs. Instead, any null value is considered unequal to (distinct from) any non-null value, and any two nulls are considered equal (not distinct). Thus the result will always be either true or false, never null.

### 9.24.6. Composite Type Comparison

\texttt{record \ operator \ record}

The SQL specification requires row-wise comparison to return NULL if the result depends on comparing two NULL values or a NULL and a non-NULL. Postgres Pro does this only when comparing the results of two row constructors (as in Section 9.24.5) or comparing a row constructor to the output of a subquery (as in Section 9.23). In other contexts where two composite-type values are compared, two NULL field values are considered equal, and a NULL is considered larger than a non-NULL. This is necessary in order to have consistent sorting and indexing behavior for composite types.

Each side is evaluated and they are compared row-wise. Composite type comparisons are allowed when the \texttt{operator} is \texttt{=}, \texttt{<>}, \texttt{<}, \texttt{<=}, \texttt{>} or \texttt{>=}, or has semantics similar to one of these. (To be specific, an operator can be a row comparison operator if it is a member of a B-tree operator class, or is the negator of the
= member of a B-tree operator class.) The default behavior of the above operators is the same as for IS [ NOT ] DISTINCT FROM for row constructors (see Section 9.24.5).

To support matching of rows which include elements without a default B-tree operator class, the following operators are defined for composite type comparison: *=, *<>*, *<*, *<=*, *>*, and *>=*. These operators compare the internal binary representation of the two rows. Two rows might have a different binary representation even though comparisons of the two rows with the equality operator is true. The ordering of rows under these comparison operators is deterministic but not otherwise meaningful. These operators are used internally for materialized views and might be useful for other specialized purposes such as replication and B-Tree deduplication (see Section 60.4.3). They are not intended to be generally useful for writing queries, though.

### 9.25. Set Returning Functions

This section describes functions that possibly return more than one row. The most widely used functions in this class are series generating functions, as detailed in Table 9.63 and Table 9.64. Other, more specialized set-returning functions are described elsewhere in this manual. See Section 7.2.1.4 for ways to combine multiple set-returning functions.

#### Table 9.63. Series Generating Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>generate_series</td>
<td>( start integer, stop integer [, step integer ] ) → setof integer</td>
</tr>
<tr>
<td>generate_series</td>
<td>( start bigint, stop bigint [, step bigint ] ) → setof bigint</td>
</tr>
<tr>
<td>generate_series</td>
<td>( start numeric, stop numeric [, step numeric ] ) → setof numeric</td>
</tr>
<tr>
<td>generate_series</td>
<td>( start timestamp, stop timestamp, step interval ) → setof timestamp</td>
</tr>
<tr>
<td>generate_series</td>
<td>( start timestamp with time zone, stop timestamp with time zone, step interval ) → setof timestamp with time zone</td>
</tr>
</tbody>
</table>

Generates a series of values from start to stop, with a step size of step. Step defaults to 1.

When step is positive, zero rows are returned if start is greater than stop. Conversely, when step is negative, zero rows are returned if start is less than stop. Zero rows are also returned if any input is NULL. It is an error for step to be zero. Some examples follow:

```sql
SELECT * FROM generate_series(2, 4);
generate_series
--------------
 2
 3
 4
(3 rows)

SELECT * FROM generate_series(5, 1, -2);
generate_series
------------
 5
 3
 1
(3 rows)

SELECT * FROM generate_series(4, 3);
generate_series
----------
(0 rows)

SELECT generate_series(1.1, 4, 1.3);
```

312
generate_series
-------------
  1.1
  2.4
  3.7
(3 rows)

-- this example relies on the date-plus-integer operator:
SELECT current_date + s.a AS dates FROM generate_series(0,14,7) AS s(a);
dates
---------
 2004-02-05
 2004-02-12
 2004-02-19
(3 rows)

SELECT * FROM generate_series('2008-03-01 00:00'::timestamp,
                            '2008-03-04 12:00', '10 hours');

generate_series
---------------------
 2008-03-01 00:00:00
 2008-03-01 10:00:00
 2008-03-01 20:00:00
 2008-03-02 06:00:00
 2008-03-02 16:00:00
 2008-03-03 02:00:00
 2008-03-03 12:00:00
 2008-03-03 22:00:00
 2008-03-04 08:00:00
(9 rows)

Table 9.64. Subscript Generating Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>generate_subscripts</td>
<td>generates a series comprising the valid subscripts of the ( dim )'th dimension of the given array.</td>
</tr>
<tr>
<td>generate_subscripts</td>
<td>generates a series comprising the valid subscripts of the ( dim )'th dimension of the given array. When ( reverse ) is true, returns the series in reverse order.</td>
</tr>
</tbody>
</table>

generate_subscripts is a convenience function that generates the set of valid subscripts for the specified dimension of the given array. Zero rows are returned for arrays that do not have the requested dimension, or if any input is NULL. Some examples follow:

-- basic usage:
SELECT generate_subscripts('(NULL,1,NULL,2)::int[], 1) AS s;
s
---
 1
 2
 3
 4
(4 rows)

-- presenting an array, the subscript and the subscripted
-- value requires a subquery:
SELECT * FROM arrays;
Functions and Operators

-- a
-------------------
{-1,-2}
(100,200,300)
(2 rows)

SELECT a AS array, s AS subscript, a[s] AS value
FROM (SELECT generate_subscripts(a, 1) AS s, a FROM arrays) foo;

<table>
<thead>
<tr>
<th>array</th>
<th>subscript</th>
<th>value</th>
</tr>
</thead>
<tbody>
<tr>
<td>{-1,-2}</td>
<td>1</td>
<td>-1</td>
</tr>
<tr>
<td>{-1,-2}</td>
<td>2</td>
<td>-2</td>
</tr>
<tr>
<td>{100,200,300}</td>
<td>1</td>
<td>100</td>
</tr>
<tr>
<td>{100,200,300}</td>
<td>2</td>
<td>200</td>
</tr>
<tr>
<td>{100,200,300}</td>
<td>3</td>
<td>300</td>
</tr>
</tbody>
</table>
(5 rows)

-- unnest a 2D array:
CREATE OR REPLACE FUNCTION unnest2(anyarray)
RETURNS SETOF anyelement AS $$
select $1[i][j]
from generate_subscripts($1,1) g1(i),
generate_subscripts($1,2) g2(j);
$$ LANGUAGE sql IMMUTABLE;
CREATE FUNCTION
SELECT * FROM unnest2(ARRAY[[1,2],[3,4]]);

unnest2
-------
1
2
3
4
(4 rows)

When a function in the FROM clause is suffixed by WITH ORDINALITY, a bigint column is appended to the function's output column(s), which starts from 1 and increments by 1 for each row of the function's output. This is most useful in the case of set returning functions such as unnest().

-- set returning function WITH ORDINALITY:
SELECT * FROM pg ls_dir('.') WITH ORDINALITY AS t(ls,n);

<table>
<thead>
<tr>
<th>ls</th>
<th>n</th>
</tr>
</thead>
<tbody>

</tr>
<tr>
<td>pg_wal</td>
<td>16</td>
</tr>
</tbody>
</table>
9.26. System Information Functions and Operators

Table 9.65 shows several functions that extract session and system information.

In addition to the functions listed in this section, there are a number of functions related to the statistics system that also provide system information. See Section 26.2.2 for more information.

Table 9.65. Session Information Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>current_catalog → name</td>
<td>Returns the name of the current database. (Databases are called “catalogs” in the SQL standard, so current_catalog is the standard’s spelling.)</td>
</tr>
<tr>
<td>current_database () → name</td>
<td>Returns the name of the current database. (Databases are called “catalogs” in the SQL standard, so current_catalog is the standard’s spelling.)</td>
</tr>
<tr>
<td>current_query () → text</td>
<td>Returns the text of the currently executing query, as submitted by the client (which might contain more than one statement).</td>
</tr>
<tr>
<td>current_role → name</td>
<td>This is equivalent to current_user.</td>
</tr>
<tr>
<td>current_schema → name</td>
<td>Returns the name of the schema that is first in the search path (or a null value if the search path is empty). This is the schema that will be used for any tables or other named objects that are created without specifying a target schema.</td>
</tr>
<tr>
<td>current_schemas (include_implicit boolean) → name[]</td>
<td>Returns an array of the names of all schemas presently in the effective search path, in their priority order. (Items in the current search_path setting that do not correspond to existing, searchable schemas are omitted.) If the Boolean argument is true, then implicitly-searched system schemas such as pg_catalog are included in the result.</td>
</tr>
<tr>
<td>current_user → name</td>
<td>Returns the user name of the current execution context.</td>
</tr>
<tr>
<td>inet_client_addr () → inet</td>
<td>Returns the IP address of the current client, or NULL if the current connection is via a Unix-domain socket.</td>
</tr>
<tr>
<td>inet_client_port () → integer</td>
<td>Returns the IP port number of the current client, or NULL if the current connection is via a Unix-domain socket.</td>
</tr>
<tr>
<td>inet_server_addr () → inet</td>
<td>Returns the IP address on which the server accepted the current connection, or NULL if the current connection is via a Unix-domain socket.</td>
</tr>
<tr>
<td>inet_server_port () → integer</td>
<td>Returns the IP port number on which the server accepted the current connection, or NULL if the current connection is via a Unix-domain socket.</td>
</tr>
<tr>
<td>pg_backend_pid () → integer</td>
<td>Returns the process ID of the server process attached to the current session.</td>
</tr>
<tr>
<td>Function</td>
<td>Description</td>
</tr>
<tr>
<td>------------------------------</td>
<td>-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>pg_blocking_pids (integer) → integer[]</td>
<td>Returns an array of the process ID(s) of the sessions that are blocking the server process with the specified process ID from acquiring a lock, or an empty array if there is no such server process or it is not blocked. One server process blocks another if it either holds a lock that conflicts with the blocked process's lock request (hard block), or is waiting for a lock that would conflict with the blocked process's lock request and is ahead of it in the wait queue (soft block). When using parallel queries the result always lists client-visible process IDs (that is, pg_backend_pid results) even if the actual lock is held or awaited by a child worker process. As a result of that, there may be duplicated PIDs in the result. Also note that when a prepared transaction holds a conflicting lock, it will be represented by a zero process ID. Frequent calls to this function could have some impact on database performance, because it needs exclusive access to the lock manager's shared state for a short time.</td>
</tr>
<tr>
<td>pg_conf_load_time () → timestamp with time zone</td>
<td>Returns the time when the server configuration files were last loaded. If the current session was alive at the time, this will be the time when the session itself re-read the configuration files (so the reading will vary a little in different sessions). Otherwise it is the time when the postmaster process re-read the configuration files.</td>
</tr>
<tr>
<td>pg_current_logfile ([text]) → text</td>
<td>Returns the path name of the log file currently in use by the logging collector. The path includes the log_directory directory and the individual log file name. The result is NULL if the logging collector is disabled. When multiple log files exist, each in a different format, <code>pg_current_logfile</code> without an argument returns the path of the file having the first format found in the ordered list: stderr, csvlog. NULL is returned if no log file has any of these formats. To request information about a specific log file format, supply either csvlog or stderr as the value of the optional parameter. The result is NULL if the log format requested is not configured in log_destination. The result reflects the contents of the current_logfiles file.</td>
</tr>
<tr>
<td>pg_my_temp_schema () → oid</td>
<td>Returns the OID of the current session's temporary schema, or zero if it has none (because it has not created any temporary tables).</td>
</tr>
<tr>
<td>pg_is_other_temp_schema (oid) → boolean</td>
<td>Returns true if the given OID is the OID of another session's temporary schema. (This can be useful, for example, to exclude other sessions' temporary tables from a catalog display.)</td>
</tr>
<tr>
<td>pg_jit_available () → boolean</td>
<td>Returns true if a JIT compiler extension is available (see Chapter 30) and the jit configuration parameter is set to on.</td>
</tr>
<tr>
<td>pg_listening_channels () → setof text</td>
<td>Returns the set of names of asynchronous notification channels that the current session is listening to.</td>
</tr>
<tr>
<td>pg_notification_queue_usage () → double precision</td>
<td>Returns the fraction (0–1) of the asynchronous notification queue's maximum size that is currently occupied by notifications that are waiting to be processed. See LISTEN and NOTIFY for more information.</td>
</tr>
<tr>
<td>pg_postmaster_start_time () → timestamp with time zone</td>
<td>Returns the time when the server started.</td>
</tr>
<tr>
<td>pg_safe_snapshot_blocking_pids (integer) → integer[]</td>
<td></td>
</tr>
<tr>
<td><strong>Function</strong></td>
<td><strong>Description</strong></td>
</tr>
<tr>
<td>-------------</td>
<td>----------------</td>
</tr>
<tr>
<td><strong>pg_trigger_depth</strong> () → integer</td>
<td>Returns the current nesting level of Postgres Pro triggers (0 if not called, directly or indirectly, from inside a trigger).</td>
</tr>
<tr>
<td><strong>session_user</strong> → name</td>
<td>Returns the session user's name.</td>
</tr>
<tr>
<td><strong>user</strong> → name</td>
<td>This is equivalent to current_user.</td>
</tr>
<tr>
<td><strong>version()</strong> → text</td>
<td>Returns a string describing the PostgreSQL server's version. You can also get this information from server_version, or for a machine-readable version use server_version_num. Software developers should use server_version_num (available since 8.2) or PQserverVersion instead of parsing the text version.</td>
</tr>
<tr>
<td><strong>pgpro_version</strong> () → text</td>
<td>Returns a string describing the Postgres Pro server's version.</td>
</tr>
<tr>
<td><strong>pgproedition()</strong> → text</td>
<td>Returns a string describing Postgres Pro edition i.e. standard or enterprise.</td>
</tr>
<tr>
<td><strong>pgpro_build</strong> () → text</td>
<td>Returns the commit ID of Postgres Pro source files.</td>
</tr>
</tbody>
</table>

**Note**

current_catalog, current_role, current_schema, current_user, session_user, and user have special syntactic status in SQL: they must be called without trailing parentheses. In Postgres Pro, parentheses can optionally be used with current_schema, but not with the others.

The session_user is normally the user who initiated the current database connection; but superusers can change this setting with SET SESSION AUTHORIZATION. The current_user is the user identifier that is applicable for permission checking. Normally it is equal to the session user, but it can be changed with SET ROLE. It also changes during the execution of functions with the attribute SECURITY DEFINER. In Unix parlance, the session user is the “real user” and the current user is the “effective user”. current_role and user are synonyms for current_user. (The SQL standard draws a distinction between current_role and current_user, but Postgres Pro does not, since it unifies users and roles into a single kind of entity.)

Table 9.66 lists functions that allow querying object access privileges programmatically. (See Section 5.7 for more information about privileges.) In these functions, the user whose privileges are being inquired about can be specified by name or by OID (pg_authid.oid), or if the name is given as public then the privileges of the PUBLIC pseudo-role are checked. Also, the user argument can be omitted entirely, in which case the current_user is assumed. The object that is being inquired about can be specified either by name or by OID, too. When specifying by name, a schema name can be included if relevant. The access privilege of interest is specified by a text string, which must evaluate to one of the appropriate
Functions and Operators

privilege keywords for the object's type (e.g., SELECT). Optionally, **WITH GRANT OPTION** can be added to a privilege type to test whether the privilege is held with grant option. Also, multiple privilege types can be listed separated by commas, in which case the result will be true if any of the listed privileges is held. (Case of the privilege string is not significant, and extra whitespace is allowed between but not within privilege names.) Some examples:

SELECT has_table_privilege('myschema.mytable', 'select');
SELECT has_table_privilege('joe', 'mytable', 'INSERT, SELECT WITH GRANT OPTION');

### Table 9.66. Access Privilege Inquiry Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>has_any_column_privilege</td>
<td><code>( [ user name or oid, ] table text or oid, privilege text ) → boolean</code></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for any column of table? This succeeds either if the privilege is held for the whole table, or if there is a column-level grant of the privilege for at least one column. Allowable privilege types are SELECT, INSERT, UPDATE, and REFERENCES.</td>
</tr>
<tr>
<td>has_column_privilege</td>
<td><code>( [ user name or oid, ] table text or oid, column text or smallint, privilege text ) → boolean</code></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for the specified table column? This succeeds either if the privilege is held for the whole table, or if there is a column-level grant of the privilege for the column. The column can be specified by name or by attribute number (pg_attribute .attnum). Allowable privilege types are SELECT, INSERT, UPDATE, and REFERENCES.</td>
</tr>
<tr>
<td>has_database_privilege</td>
<td><code>( [ user name or oid, ] database text or oid, privilege text ) → boolean</code></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for database? Allowable privilege types are CREATE, CONNECT, TEMPORARY, and TEMP (which is equivalent to TEMPORARY).</td>
</tr>
<tr>
<td>has_foreign_data_wrapper_privilege</td>
<td><code>( [ user name or oid, ] fdw text or oid, privilege text ) → boolean</code></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for foreign-data wrapper? The only allowable privilege type is USAGE.</td>
</tr>
<tr>
<td>has_function_privilege</td>
<td><code>( [ user name or oid, ] function text or oid, privilege text ) → boolean</code></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for function? The only allowable privilege type is EXECUTE. When specifying a function by name rather than by OID, the allowed input is the same as for the regprocedure data type (see Section 8.19). An example is: SELECT has_function_privilege('joeuser', 'myfunc(int, text)', 'execute');</td>
</tr>
<tr>
<td>has_language_privilege</td>
<td><code>( [ user name or oid, ] language text or oid, privilege text ) → boolean</code></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for language? The only allowable privilege type is USAGE.</td>
</tr>
<tr>
<td>has_schema_privilege</td>
<td><code>( [ user name or oid, ] schema text or oid, privilege text ) → boolean</code></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for schema? Allowable privilege types are CREATE and USAGE.</td>
</tr>
<tr>
<td>has_sequence_privilege</td>
<td><code>( [ user name or oid, ] sequence text or oid, privilege text ) → boolean</code></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for sequence? Allowable privilege types are USAGE, SELECT, and UPDATE.</td>
</tr>
<tr>
<td>has_server_privilege</td>
<td><code>( [ user name or oid, ] server text or oid, privilege text ) → boolean</code></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for foreign server? The only allowable privilege type is USAGE.</td>
</tr>
<tr>
<td>has_table_privilege</td>
<td><code>( [ user name or oid, ] table text or oid, privilege text ) → boolean</code></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for table? Allowable privilege types are SELECT, INSERT, UPDATE, DELETE, TRUNCATE, REFERENCES, and TRIGGER.</td>
</tr>
</tbody>
</table>
### Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>has_tablespace_privilege</code></td>
<td><strong>([user name or oid,] tablespace text or oid, privilege text) → boolean</strong></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for tablespace? The only allowable privilege type is <strong>CREATE</strong>.</td>
</tr>
<tr>
<td><code>has_type_privilege</code></td>
<td><strong>([user name or oid,] type text or oid, privilege text) → boolean</strong></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for data type? The only allowable privilege type is <strong>USAGE</strong>. When</td>
</tr>
<tr>
<td></td>
<td>specifying a type by name rather than by OID, the allowed input is the same as for the regtype</td>
</tr>
<tr>
<td></td>
<td>data type (see Section 8.19).</td>
</tr>
<tr>
<td><code>pg_has_role</code></td>
<td><strong>([user name or oid,] role text or oid, privilege text) → boolean</strong></td>
</tr>
<tr>
<td></td>
<td>Does user have privilege for role? Allowable privilege types are <strong>MEMBER</strong> and <strong>USAGE</strong>. <strong>MEMBER</strong> denotes direct or indirect membership in the role (that is, the right to do SET ROLE), while <strong>USAGE</strong> denotes whether the privileges of the role are immediately available without doing SET ROLE. This function does not allow the special case of setting user to public, because the PUBLIC pseudo-role can never be a member of real roles.</td>
</tr>
<tr>
<td><code>row_security_active</code></td>
<td><strong>(table text or oid) → boolean</strong></td>
</tr>
<tr>
<td></td>
<td>Is row-level security active for the specified table in the context of the current user and</td>
</tr>
<tr>
<td></td>
<td>current environment?</td>
</tr>
</tbody>
</table>

Table 9.67 shows the operators available for the `aclitem` type, which is the catalog representation of access privileges. See Section 5.7 for information about how to read access privilege values.

#### Table 9.67. `aclitem` Operators

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>aclitem = aclitem</code></td>
<td><strong>→ boolean</strong></td>
</tr>
<tr>
<td></td>
<td>Are <code>aclitem</code>s equal? (Notice that type <code>aclitem</code> lacks the usual set of comparison operators; it</td>
</tr>
<tr>
<td></td>
<td>has only equality. In turn, <code>aclitem</code> arrays can only be compared for equality.)</td>
</tr>
<tr>
<td></td>
<td>'calvin=r<em>w/hobbes'::aclitem = 'calvin=r</em>w*/hobbes'::aclitem → f</td>
</tr>
<tr>
<td><code>aclitem[] @&gt; aclitem</code></td>
<td><strong>→ boolean</strong></td>
</tr>
<tr>
<td></td>
<td>Does array contain the specified privileges? (This is true if there is an array entry that</td>
</tr>
<tr>
<td></td>
<td>matches the <code>aclitem</code>s grantee and grantor, and has at least the specified set of privileges.)</td>
</tr>
<tr>
<td></td>
<td>'{calvin=r<em>w/hobbes,hobbes=r</em>w*/postgres}'::aclitem[] @&gt; 'calvin=r*/hobbes'::aclitem → t</td>
</tr>
<tr>
<td><code>aclitem[] ~ aclitem</code></td>
<td><strong>→ boolean</strong></td>
</tr>
<tr>
<td></td>
<td>This is a deprecated alias for <code>@&gt;</code>.</td>
</tr>
<tr>
<td></td>
<td>'{calvin=r<em>w/hobbes,hobbes=r</em>w*/postgres}'::aclitem[] ~ 'calvin=r*/hobbes'::aclitem → t</td>
</tr>
</tbody>
</table>

Table 9.68 shows some additional functions to manage the `aclitem` type.

#### Table 9.68. `aclitem` Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>acldefault</code> ([type &quot;char&quot;, ownerId oid]) → aclitem[]</td>
<td>Constructs an <code>aclitem</code> array holding the default access privileges for an object of type <code>type</code> belonging to the role with OID <code>ownerId</code>. This represents the access privileges that will be assumed when an object's ACL entry is null. (The default access privileges are described in Section 5.7.) The <code>type</code> parameter must be one of 'c' for <code>COLUMN</code>, 'r' for <code>TABLE</code> and table-like objects, 's' for <code>SEQUENCE</code>, 'd' for <code>DATABASE</code>, 'f' for <code>FUNCTION</code> or <code>PROCEDURE</code>, 'l' for <code>LANGUAGE</code>, 'L'</td>
</tr>
</tbody>
</table>
Functions and Operators

### Function Description

For LARGE OBJECT, 'n' for SCHEMA, 't' for TABLESPACE, 'F' for FOREIGN DATA WRAPPER, 'S' for FOREIGN SERVER, or 'T' for TYPE or DOMAIN.

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>aclexplode( aclitem[] ) → setof record ( grantor oid, grantee oid, privilege_type text, is_grantable boolean )</td>
<td>Returns the aclitem array as a set of rows. If the grantee is the pseudo-role PUBLIC, it is represented by zero in the grantee column. Each granted privilege is represented as SELECT, INSERT, etc. Note that each privilege is broken out as a separate row, so only one keyword appears in the privilege_type column.</td>
</tr>
<tr>
<td>makeaclitem( grantee oid, grantor oid, privileges text, is_grantable boolean ) → aclitem</td>
<td>Constructs an aclitem with the given properties.</td>
</tr>
</tbody>
</table>

Table 9.69 shows functions that determine whether a certain object is visible in the current schema search path. For example, a table is said to be visible if its containing schema is in the search path and no table of the same name appears earlier in the search path. This is equivalent to the statement that the table can be referenced by name without explicit schema qualification. Thus, to list the names of all visible tables:

```sql
SELECT relname FROM pg_class WHERE pg_table_is_visible(oid);
```

For functions and operators, an object in the search path is said to be visible if there is no object of the same name and argument data type(s) earlier in the path. For operator classes and families, both the name and the associated index access method are considered.

### Table 9.69. Schema Visibility Inquiry Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_collation_is_visible ( collation oid ) → boolean</td>
<td>Is collation visible in search path?</td>
</tr>
<tr>
<td>pg_conversion_is_visible ( conversion oid ) → boolean</td>
<td>Is conversion visible in search path?</td>
</tr>
<tr>
<td>pg_function_is_visible ( function oid ) → boolean</td>
<td>Is function visible in search path? (This also works for procedures and aggregates.)</td>
</tr>
<tr>
<td>pg_opclass_is_visible ( opclass oid ) → boolean</td>
<td>Is operator class visible in search path?</td>
</tr>
<tr>
<td>pg_operator_is_visible ( operator oid ) → boolean</td>
<td>Is operator visible in search path?</td>
</tr>
<tr>
<td>pg_opfamily_is_visible ( opclass oid ) → boolean</td>
<td>Is operator family visible in search path?</td>
</tr>
<tr>
<td>pg_statistics_obj_is_visible ( stat oid ) → boolean</td>
<td>Is statistics object visible in search path?</td>
</tr>
<tr>
<td>pg_table_is_visible ( table oid ) → boolean</td>
<td>Is table visible in search path? (This works for all types of relations, including views, materialized views, indexes, sequences and foreign tables.)</td>
</tr>
<tr>
<td>pg_ts_config_is_visible ( config oid ) → boolean</td>
<td>Is text search configuration visible in search path?</td>
</tr>
<tr>
<td>pg_ts_dict_is_visible ( dict oid ) → boolean</td>
<td>Is text search dictionary visible in search path?</td>
</tr>
</tbody>
</table>
Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_ts_parser_is_visible</td>
<td>(parser oid) → boolean</td>
</tr>
<tr>
<td>Is text search parser visible in search path?</td>
<td></td>
</tr>
<tr>
<td>pg_ts_template_is_visible</td>
<td>(template oid) → boolean</td>
</tr>
<tr>
<td>Is text search template visible in search path?</td>
<td></td>
</tr>
<tr>
<td>pg_type_is_visible</td>
<td>(type oid) → boolean</td>
</tr>
<tr>
<td>Is type (or domain) visible in search path?</td>
<td></td>
</tr>
</tbody>
</table>

All these functions require object OIDs to identify the object to be checked. If you want to test an object by name, it is convenient to use the OID alias types (regclass, regtype, regprocedure, regoperator, regconfig, or regdictionary), for example:

```
SELECT pg_type_is_visible('myschema.widget'::regtype);
```

Note that it would not make much sense to test a non-schema-qualified type name in this way — if the name can be recognized at all, it must be visible.

Table 9.70 lists functions that extract information from the system catalogs.

Table 9.70. System Catalog Information Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>format_type</td>
<td>(type oid, typemod integer) → text</td>
</tr>
<tr>
<td>Returns the SQL name for a data type that is identified by its type OID and possibly a type modifier. Pass NULL for the type modifier if no specific modifier is known.</td>
<td></td>
</tr>
<tr>
<td>pg_get_catalog_foreign_keys</td>
<td>() → setof record (fktable regclass, fkcols text[], pktable regclass, pkcols text[], is_array boolean, is_opt boolean)</td>
</tr>
<tr>
<td>Returns a set of records describing the foreign key relationships that exist within the PostgreSQL system catalogs. The fktable column contains the name of the referencing catalog, and the fkcols column contains the name(s) of the referencing column(s). Similarly, the pktable column contains the name of the referenced catalog, and the pkcols column contains the name(s) of the referenced column(s). If is_array is true, the last referencing column is an array, each of whose elements should match some entry in the referenced catalog. If is_opt is true, the referencing column(s) are allowed to contain zeroes instead of a valid reference.</td>
<td></td>
</tr>
<tr>
<td>pg_get_constraintdef</td>
<td>(constraint oid [, pretty boolean ]) → text</td>
</tr>
<tr>
<td>Reconstructs the creating command for a constraint. (This is a decompiled reconstruction, not the original text of the command.)</td>
<td></td>
</tr>
<tr>
<td>pg_get_expr</td>
<td>(expr pg_node_tree , relation oid [, pretty boolean ]) → text</td>
</tr>
<tr>
<td>Decomposes the internal form of an expression stored in the system catalogs, such as the default value for a column. If the expression might contain Vars, specify the OID of the relation they refer to as the second parameter; if no Vars are expected, passing zero is sufficient.</td>
<td></td>
</tr>
<tr>
<td>pg_get_functiondef</td>
<td>(func oid) → text</td>
</tr>
<tr>

## Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_get_function_result</td>
<td>Reconstructs the argument list necessary to identify a function or procedure, in the form it would need to appear in within commands such as <code>ALTER FUNCTION</code>. This form omits default values.</td>
</tr>
<tr>
<td>pg_get_indexdef</td>
<td>Reconstructs the <code>RETURNS</code> clause of a function, in the form it would need to appear in within <code>CREATE FUNCTION</code>. Returns <code>NULL</code> for a procedure.</td>
</tr>
<tr>
<td>pg_get_keywords</td>
<td>Reconstructs the creating command for an index. (This is a decompiled reconstruction, not the original text of the command.) If <code>column</code> is supplied and is not zero, only the definition of that column is reconstructed.</td>
</tr>
<tr>
<td>pg_get_ruledef</td>
<td>Reconstructs the creating command for a rule. (This is a decompiled reconstruction, not the original text of the command.)</td>
</tr>
<tr>
<td>pg_get_serial_sequence</td>
<td>Returns the name of the sequence associated with a column, or <code>NULL</code> if no sequence is associated with the column. If the column is an identity column, the associated sequence is the sequence internally created for that column. For columns created using one of the serial types (<code>serial</code>, <code>smallserial</code>, <code>bigserial</code>), it is the sequence created for that serial column definition. In the latter case, the association can be modified or removed with <code>ALTER SEQUENCE OWNED BY</code>. (This function probably should have been called <code>pg_get_owned_sequence</code>; its current name reflects the fact that it has historically been used with serial-type columns.) The first parameter is a table name with optional schema, and the second parameter is a column name. Because the first parameter potentially contains both schema and table names, it is parsed per usual SQL rules, meaning it is lower-cased by default. The second parameter, being just a column name, is treated literally and so has its case preserved. The result is suitably formatted for passing to the sequence functions (see Section 9.17). A typical use is in reading the current value of the sequence for an identity or serial column, for example: <code>SELECT currval(pg_get_serial_sequence('sometable', 'id'));</code></td>
</tr>
<tr>
<td>pg_get_statisticsobjdef</td>
<td>Reconstructs the creating command for an extended statistics object. (This is a decompiled reconstruction, not the original text of the command.)</td>
</tr>
<tr>
<td>pg_get_triggerdef</td>
<td>Reconstructs the creating command for a trigger. (This is a decompiled reconstruction, not the original text of the command.)</td>
</tr>
<tr>
<td>pg_get_userbyid</td>
<td>Returns a role’s name given its OID.</td>
</tr>

Also unlike the cast, this does not accept a numeric OID as input.</td>
</tr>
</tbody>
</table>

Most of the functions that reconstruct (decompile) database objects have an optional pretty flag, which if true causes the result to be “pretty-printed”. Pretty-printing suppresses unnecessary parentheses and adds whitespace for legibility. The pretty-printed format is more readable, but the default format is more likely to be interpreted the same way by future versions of Postgres Pro; so avoid using pretty-printed output for dump purposes. Passing false for the pretty parameter yields the same result as omitting the parameter.

Table 9.71. Index Column Properties

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>

#### Table 9.74 lists functions related to database object identification and addressing.

#### Table 9.74. Object Information and Addressing Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_describe_object (classid oid, objid oid, objsubid integer) \rightarrow text</td>
<td>Returns a textual description of a database object identified by catalog OID, object OID, and sub-object ID (such as a column number within a table; the sub-object ID is zero when referring to a whole object). This description is intended to be human-readable, and might be translated, depending on server configuration. This is especially useful to determine the identity of an object referenced in the <code>pg_depend</code> catalog. This function returns <code>NULL</code> values for undefined objects.</td>
</tr>
<tr>
<td>pg_identify_object (classid oid, objid oid, objsubid integer) \rightarrow record (type text, schema text, name text, identity text)</td>
<td>Returns a row containing enough information to uniquely identify the database object specified by catalog OID, object OID and sub-object ID. This information is intended to be machine-readable, and is never translated. <code>type</code> identifies the type of database object; <code>schema</code> is the schema name that the object belongs in, or <code>NULL</code> for object types that do not belong to schemas; <code>name</code> is the name of the object, quoted if necessary, if the name (along with schema name, if pertinent) is sufficient to uniquely identify the object, otherwise <code>NULL</code>; <code>identity</code> is the complete object identity, with the precise format depending on object type, and each name within the format being schema-qualified and quoted as necessary. Undefined objects are identified with <code>NULL</code> values.</td>
</tr>
<tr>
<td>pg_identify_object_as_address (classid oid, objid oid, objsubid integer) \rightarrow record (type text, object_names text[], object_args text[])</td>
<td>Returns a row containing enough information to uniquely identify the database object specified by catalog OID, object OID and sub-object ID. The returned information is independent of the current server; that is, it could be used to identify an identically named object in another server. <code>type</code> identifies the type of database object; <code>object_names</code> and <code>object_args</code> are text arrays that together form a reference to the object. These three values can be passed to <code>pg_get_object_address</code> to obtain the internal address of the object.</td>
</tr>
<tr>
<td>pg_get_object_address (type text, object_names text[], object_args text[]) \rightarrow record (classid oid, objid oid, objsubid integer)</td>
<td>Returns a row containing enough information to uniquely identify the database object specified by a type code and object name and argument arrays. The returned values are the</td>
</tr>
</tbody>
</table>
The functions shown in Table 9.75 extract comments previously stored with the COMMENT command. A null value is returned if no comment could be found for the specified parameters.

### Table 9.75. Comment Information Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>col_description (table oid, column integer) → text</code></td>
<td>Returns the comment for a table column, which is specified by the OID of its table and its column number. (obj_description cannot be used for table columns, since columns do not have OIDs of their own.)</td>
</tr>
<tr>
<td><code>obj_description (object oid, catalog name) → text</code></td>
<td>Returns the comment for a database object specified by its OID and the name of the containing system catalog. For example, <code>obj_description(123456, 'pg_class')</code> would retrieve the comment for the table with OID 123456.</td>
</tr>
<tr>
<td><code>obj_description (object oid) → text</code></td>
<td>Returns the comment for a database object specified by its OID alone. This is deprecated since there is no guarantee that OIDs are unique across different system catalogs; therefore, the wrong comment might be returned.</td>
</tr>
<tr>
<td><code>shobj_description (object oid, catalog name) → text</code></td>
<td>Returns the comment for a shared database object specified by its OID and the name of the containing system catalog. This is just like obj_description except that it is used for retrieving comments on shared objects (that is, databases, roles, and tablespaces). Some system catalogs are global to all databases within each cluster, and the descriptions for objects in them are stored globally as well.</td>
</tr>
</tbody>
</table>

The functions shown in Table 9.76 provide server transaction information in an exportable form. The main use of these functions is to determine which transactions were committed between two snapshots.

### Table 9.76. Transaction ID and Snapshot Information Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pg_current_xact_id () → xid8</code></td>
<td>Returns the current transaction's ID. It will assign a new one if the current transaction does not have one already (because it has not performed any database updates).</td>
</tr>
<tr>
<td><code>pg_current_xact_id_if_assigned () → xid8</code></td>
<td>Returns the current transaction's ID, or NULL if no ID is assigned yet. (It's best to use this variant if the transaction might otherwise be read-only, to avoid unnecessary consumption of an XID.)</td>
</tr>
<tr>
<td><code>pg_xact_status (xid8) → text</code></td>
<td>Reports the commit status of a recent transaction. The result is one of in progress, committed, or aborted, provided that the transaction is recent enough that the system retains the commit status of that transaction. If it is old enough that no references to the transaction survive in the system and the commit status information has been discarded, the result is NULL. Applications might use this function, for example, to determine whether their transaction committed or aborted after the application and database server become disconnected.</td>
</tr>
</tbody>
</table>
### Function Description

Disconnected while a COMMIT is in progress. Note that prepared transactions are reported as in progress; applications must check `pg_prepared_xacts` if they need to determine whether a transaction ID belongs to a prepared transaction.

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pg_current_snapshot</code> () → pg_snapshot</td>
<td>Returns a current snapshot, a data structure showing which transaction IDs are now in-progress.</td>
</tr>
<tr>
<td><code>pg_snapshot_xip</code> (pg_snapshot ) → setof xid8</td>
<td>Returns the set of in-progress transaction IDs contained in a snapshot.</td>
</tr>
<tr>
<td><code>pg_snapshot_xmax</code> (pg_snapshot ) → xid8</td>
<td>Returns the xmax of a snapshot.</td>
</tr>
<tr>
<td><code>pg_snapshot_xmin</code> (pg_snapshot ) → xid8</td>
<td>Returns the xmin of a snapshot.</td>
</tr>
<tr>
<td><code>pg_visible_in_snapshot</code> (xid8, pg_snapshot ) → boolean</td>
<td>Is the given transaction ID visible according to this snapshot (that is, was it completed before the snapshot was taken)? Note that this function will not give the correct answer for a subtransaction ID.</td>
</tr>
</tbody>
</table>

The internal transaction ID type `xid` is 32 bits wide and wraps around every 4 billion transactions. However, the functions shown in Table 9.76 use a 64-bit type `xid8` that does not wrap around during the life of an installation, and can be converted to `xid` by casting if required. The data type `pg_snapshot` stores information about transaction ID visibility at a particular moment in time. Its components are described in Table 9.77. `pg_snapshot’s textual representation` is `xmin:ximax:xip_list`. For example, `10:20:10,14,15` means `xmin=10, xmax=20, xip_list=10, 14, 15`.

#### Table 9.77. Snapshot Components

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xmin</td>
<td>Lowest transaction ID that was still active. All transaction IDs less than xmin are either committed and visible, or rolled back and dead.</td>
</tr>
<tr>
<td>xmax</td>
<td>One past the highest completed transaction ID. All transaction IDs greater than or equal to xmax had not yet completed as of the time of the snapshot, and thus are invisible.</td>
</tr>
<tr>
<td>xip_list</td>
<td>Transactions in progress at the time of the snapshot. A transaction ID that is xmin &lt;= X &lt; xmax and not in this list was already completed at the time of the snapshot, and thus is either visible or dead according to its commit status. This list does not include the transaction IDs of subtransactions.</td>
</tr>
</tbody>
</table>

In releases of PostgreSQL before 13 there was no `xid8` type, so variants of these functions were provided that used `bigint` to represent a 64-bit XID, with a correspondingly distinct snapshot data type `txid_snapshot`. These older functions have `txid` in their names. They are still supported for backward compatibility, but may be removed from a future release. See Table 9.78.

#### Table 9.78. Deprecated Transaction ID and Snapshot Information Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>

</tr>
<tr>
<td><code>txid_status</code></td>
<td>(bigint)→ text See <code>pg_xact_status()</code></td>
</tr>
</tbody>
</table>

The functions shown in Table 9.79 provide information about when past transactions were committed. They only provide useful data when the `track_commit_timestamp` configuration option is enabled, and only for transactions that were committed after it was enabled.

### Table 9.79. Committed Transaction Information Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pg_xact_commit_timestamp</code></td>
<td>(xid)→ timestamp with time zone Returns the commit timestamp of a transaction.</td>
</tr>
<tr>
<td><code>pg_xact_commit_timestamp_origin</code></td>
<td>(xid)→ record (timestamp, timestamp with time zone, roIdent oid) Returns the commit timestamp and replication origin of a transaction.</td>
</tr>
<tr>
<td><code>pg_last_committed_xact</code></td>
<td>()→ record (xid, timestamp, timestamp with time zone, roIdent oid) Returns the transaction ID, commit timestamp and replication origin of the latest committed transaction.</td>
</tr>
</tbody>
</table>

The functions shown in Table 9.80 print information initialized during `initdb`, such as the catalog version. They also show information about write-ahead logging and checkpoint processing. This information is cluster-wide, not specific to any one database. These functions provide most of the same information, from the same source, as the `pg_controldata` application.

### Table 9.80. Control Data Functions

<table>
<thead>

### 9.27. System Administration Functions

The functions described in this section are used to control and monitor a Postgres Pro installation.

#### 9.27.1. Configuration Settings Functions

Table 9.85 shows the functions available to query and alter run-time configuration parameters.

Table 9.85. Configuration Settings Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>current_setting (setting_name text [, missing_ok boolean]) → text</td>
<td>Returns the current value of the setting <code>setting_name</code>. If there is no such setting, <code>current_setting</code> throws an error unless <code>missing_ok</code> is supplied and is true (in which case NULL is returned). This function corresponds to the SQL command <code>SHOW</code>.</td>
<td><code>current_setting('datestyle') → ISO, MDY</code></td>
</tr>
<tr>
<td>set_config (setting_name text, new_value text, is_local boolean) → text</td>
<td>Sets the parameter <code>setting_name</code> to <code>new_value</code>, and returns that value. If <code>is_local</code> is true, the new value will only apply during the current transaction. If you want the new value to apply for the rest of the current session, use <code>false</code> instead. This function corresponds to the SQL command <code>SET</code>.</td>
<td><code>set_config('log_statement_stats', 'off', false) → off</code></td>
</tr>
</tbody>
</table>

#### 9.27.2. Server Signaling Functions

The functions shown in Table 9.86 send control signals to other server processes. Use of these functions is restricted to superusers by default but access may be granted to others using `GRANT`, with noted exceptions.

Each of these functions returns `true` if the signal was successfully sent and `false` if sending the signal failed.
Table 9.86. Server Signaling Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_cancel_backend (pid integer) → boolean</td>
<td>Cancels the current query of the session whose backend process has the specified process ID. This is also allowed if the calling role is a member of the role whose backend is being canceled or the calling role has been granted pg_signal_backend, however only superusers can cancel superuser backends.</td>
</tr>
<tr>
<td>pg_log_backend_memory_contexts (pid integer) → boolean</td>
<td>Requests to log the memory contexts of the backend with the specified process ID. These memory contexts will be logged at LOG message level. They will appear in the server log based on the log configuration set (See Section 18.8 for more information), but will not be sent to the client regardless of client_min_messages. Only superusers can request to log the memory contexts.</td>
</tr>
<tr>
<td>pg_reload_conf () → boolean</td>
<td>Causes all processes of the PostgreSQL server to reload their configuration files. (This is initiated by sending a SIGHUP signal to the postmaster process, which in turn sends SIGHUP to each of its children.) You can use the pg_file_settings and pg_hba_file_rules views to check the configuration files for possible errors, before reloading.</td>
</tr>
<tr>
<td>pg_rotate_logfile () → boolean</td>
<td>Signals the log-file manager to switch to a new output file immediately. This works only when the built-in log collector is running, since otherwise there is no log-file manager subprocess.</td>
</tr>
<tr>
<td>pg_terminate_backend (pid integer, timeout bigint DEFAULT 0) → boolean</td>
<td>Terminates the session whose backend process has the specified process ID. This is also allowed if the calling role is a member of the role whose backend is being terminated or the calling role has been granted pg_signal_backend, however only superusers can terminate superuser backends. If timeout is not specified or zero, this function returns true whether the process actually terminates or not, indicating only that the sending of the signal was successful. If the timeout is specified (in milliseconds) and greater than zero, the function waits until the process is actually terminated or until the given time has passed. If the process is terminated, the function returns true. On timeout, a warning is emitted and false is returned.</td>
</tr>
</tbody>
</table>

pg_cancel_backend and pg_terminate_backend send signals (SIGINT or SIGTERM respectively) to backend processes identified by process ID. The process ID of an active backend can be found from the pid column of the pg_stat_activity view, or by listing the postgres processes on the server (using ps on Unix or the Task Manager on Windows). The role of an active backend can be found from the usename column of the pg_stat_activity view.

pg_log_backend_memory_contexts can be used to log the memory contexts of a backend process. For example:

```
postgres=# SELECT pg_log_backend_memory_contexts(pg_backend_pid());
```

```
t
(1 row)
```

One message for each memory context will be logged. For example:

```
LOG: logging memory contexts of PID 10377
STATEMENT: SELECT pg_log_backend_memory_contexts(pg_backend_pid());
LOG: level: 0; TopMemoryContext: 80800 total in 6 blocks; 14432 free (5 chunks); 66368 used
LOG: level: 1; pgstat TabStatusArray lookup hash table: 8192 total in 1 blocks; 1408 free (0 chunks); 6784 used
```
Functions and Operators

LOG: level: 1; TopTransactionContext: 8192 total in 1 blocks; 7720 free (1 chunks); 472 used
LOG: level: 1; RowDescriptionContext: 8192 total in 1 blocks; 6880 free (0 chunks); 1312 used
LOG: level: 1; MessageContext: 16384 total in 2 blocks; 5152 free (0 chunks); 11232 used
LOG: level: 1; Operator class cache: 8192 total in 1 blocks; 512 free (0 chunks); 7680 used
LOG: level: 1; smgr relation table: 16384 total in 2 blocks; 4544 free (3 chunks); 11840 used
LOG: level: 1; TransactionAbortContext: 32768 total in 1 blocks; 32504 free (0 chunks); 264 used
...
LOG: level: 1; ErrorContext: 8192 total in 1 blocks; 7928 free (3 chunks); 264 used
LOG: Grand total: 1651920 bytes in 201 blocks; 622360 free (88 chunks); 1029560 used

If there are more than 100 child contexts under the same parent, the first 100 child contexts are logged, along with a summary of the remaining contexts. Note that frequent calls to this function could incur significant overhead, because it may generate a large number of log messages.

9.27.3. Backup Control Functions

The functions shown in Table 9.87 assist in making on-line backups. These functions cannot be executed during recovery (except non-exclusive pg_start_backup, non-exclusive pg_stop_backup, pg_is_in_backup, pg_backup_start_time and pg_wal_lsn_diff).

For details about proper usage of these functions, see Section 24.3.

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_create_restore_point</td>
<td>(name text) → pg_lsn</td>
</tr>
<tr>
<td>Creates a named marker record in the write-ahead log that can later be used as a recovery target, and returns the corresponding write-ahead log location. The given name can then be used with recovery_target_name to specify the point up to which recovery will proceed. Avoid creating multiple restore points with the same name, since recovery will stop at the first one whose name matches the recovery target. This function is restricted to superusers by default, but other users can be granted EXECUTE to run the function.</td>
<td></td>
</tr>
<tr>
<td>pg_current_wal_flush_lsn</td>
<td>() → pg_lsn</td>
</tr>
<tr>
<td>Returns the current write-ahead log flush location (see notes below).</td>
<td></td>
</tr>
<tr>
<td>pg_current_wal_insert_lsn</td>
<td>() → pg_lsn</td>
</tr>
<tr>
<td>Returns the current write-ahead log insert location (see notes below).</td>
<td></td>
</tr>
<tr>
<td>pg_current_wal_lsn</td>
<td>() → pg_lsn</td>
</tr>
<tr>
<td>Returns the current write-ahead log write location (see notes below).</td>
<td></td>
</tr>
<tr>
<td>pg_start_backup</td>
<td>(label text [, fast boolean [, exclusive boolean ]]) → pg_lsn</td>
</tr>
</tbody>
</table>
| Prepares the server to begin an on-line backup. The only required parameter is an arbitrary user-defined label for the backup. (Typically this would be the name under which the backup dump file will be stored.) If the optional second parameter is given as true, it specifies executing pg_start_backup as quickly as possible. This forces an immediate checkpoint which will cause a spike in I/O operations, slowing any concurrently executing queries. The optional third parameter specifies whether to perform an exclusive or non-exclusive backup (default is exclusive). When used in exclusive mode, this function writes a backup label file (backup_label) and, if there are any links in the pg_tblspc/ directory, a tablespace map file (tablespace_map) into the database cluster's data directory, then performs a checkpoint, and then returns the
<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>backup's starting write-ahead log location.</td>
<td>(The user can ignore this result value, but it is provided in case it is useful.) When used in non-exclusive mode, the contents of these files are instead returned by the <code>pg_stop_backup</code> function, and should be copied to the backup area by the user. This function is restricted to superusers by default, but other users can be granted EXECUTE to run the function.</td>
</tr>
<tr>
<td><code>pg_stop_backup</code></td>
<td>(exclusive boolean [, wait_for_archive boolean ]) → setof record (lsn, labelfile text, spcmapfile text) Finishes performing an exclusive or non-exclusive on-line backup. The exclusive parameter must match the previous <code>pg_start_backup</code> call. In an exclusive backup, <code>pg_stop_backup</code> removes the backup label file and, if it exists, the tablespace map file created by <code>pg_start_backup</code>. In a non-exclusive backup, the desired contents of these files are returned as part of the result of the function, and should be written to files in the backup area (not in the data directory). There is an optional second parameter of type boolean. If false, the function will return immediately after the backup is completed, without waiting for WAL to be archived. This behavior is only useful with backup software that independently monitors WAL archiving. Otherwise, WAL required to make the backup consistent might be missing and make the backup useless. By default or when this parameter is true, <code>pg_stop_backup</code> will wait for WAL to be archived when archiving is enabled. (On a standby, this means that it will wait only when <code>archive_mode = always</code>. If write activity on the primary is low, it may be useful to run <code>pg_switch_wal</code> on the primary in order to trigger an immediate segment switch.) When executed on a primary, this function also creates a backup history file in the write-ahead log archive area. The history file includes the label given to <code>pg_start_backup</code>, the starting and ending write-ahead log locations for the backup, and the starting and ending times of the backup. After recording the ending location, the current write-ahead log insertion point is automatically advanced to the next write-ahead log file, so that the ending write-ahead log file can be archived immediately to complete the backup. The result of the function is a single record. The <code>lsn</code> column holds the backup's ending write-ahead log location (which again can be ignored). The second and third columns are NULL when ending an exclusive backup; after a non-exclusive backup they hold the desired contents of the label and tablespace map files. This function is restricted to superusers by default, but other users can be granted EXECUTE to run the function.</td>
</tr>
<tr>
<td><code>pg_stop_backup</code></td>
<td>() → <code>pg_lsn</code> Finishes performing an exclusive on-line backup. This simplified version is equivalent to <code>pg_stop_backup(true, true)</code>, except that it only returns the <code>pg_lsn</code> result. This function is restricted to superusers by default, but other users can be granted EXECUTE to run the function.</td>
</tr>
<tr>
<td><code>pg_is_in_backup</code></td>
<td>() → boolean Returns true if an on-line exclusive backup is in progress.</td>
</tr>
<tr>
<td><code>pg_backup_start_time</code></td>
<td>() → <code>timestamp with time zone</code> Returns the start time of the current on-line exclusive backup if one is in progress, otherwise NULL.</td>
</tr>
<tr>
<td><code>pg_switch_wal</code></td>
<td>() → <code>pg_lsn</code> Forces the server to switch to a new write-ahead log file, which allows the current file to be archived (assuming you are using continuous archiving). The result is the ending write-ahead log location plus 1 within the just-completed write-ahead log file. If there has been no write-ahead log activity since the last write-ahead log switch, <code>pg_switch_wal</code> does nothing and returns the start location of the write-ahead log file currently in use.</td>
</tr>
<tr>
<td>Function</td>
<td>Description</td>
</tr>
<tr>
<td>----------------------------------</td>
<td>-----------------------------------------------------------------------------</td>
</tr>
<tr>
<td>This function is restricted to</td>
<td>This function is restricted to superusers by default, but other users can be</td>
</tr>
<tr>
<td>superusers by default, but other</td>
<td>granted EXECUTE to run the function.</td>
</tr>
<tr>
<td>users can be granted EXECUTE</td>
<td></td>
</tr>
<tr>
<td>to run the function.</td>
<td></td>
</tr>
<tr>
<td>pg_walfile_name (lsn pg_lsn) →</td>
<td>Converts a write-ahead log location to the name of the WAL file holding that</td>
</tr>
<tr>
<td>text</td>
<td>location.</td>
</tr>
<tr>
<td>pg_walfile_name_offset (lsn</td>
<td>Converts a write-ahead log location to a WAL file name and byte offset within</td>
</tr>
<tr>
<td>pg_lsn) → record (file_name</td>
<td>that file.</td>
</tr>
<tr>
<td>text, file_offset integer)</td>
<td></td>
</tr>
<tr>
<td>pg_wal_lsn_diff (lsn1 pg_lsn,</td>
<td>Calculates the difference in bytes (lsn1 - lsn2) between two write-ahead log</td>
</tr>
<tr>
<td>lsn2 pg_lsn) → numeric</td>
<td>locations. This can be used with pg_stat_replication or some of the functions</td>
</tr>
<tr>
<td></td>
<td>shown in Table 9.87 to get the replication lag.</td>
</tr>
</tbody>
</table>

pg_current_wal_lsn displays the current write-ahead log write location in the same format used by the above functions. Similarly, pg_current_wal_insert_lsn displays the current write-ahead log insertion location and pg_current_wal_flush_lsn displays the current write-ahead log flush location. The insertion location is the “logical” end of the write-ahead log at any instant, while the write location is the end of what has actually been written out from the server’s internal buffers, and the flush location is the last location known to be written to durable storage. The write location is the end of what can be examined from outside the server, and is usually what you want if you are interested in archiving partially-complete write-ahead log files. The insertion and flush locations are made available primarily for server debugging purposes. These are all read-only operations and do not require superuser permissions.

You can use pg_walfile_name_offset to extract the corresponding write-ahead log file name and byte offset from a pg_lsn value. For example:

```
postgres=# SELECT * FROM pg_walfile_name_offset(pg_stop_backup());
             file_name       | file_offset
-----------------+-----------------|
00000001000000000000000D |    4039624
(1 row)
```

Similarly, pg_walfile_name extracts just the write-ahead log file name. When the given write-ahead log location is exactly at a write-ahead log file boundary, both these functions return the name of the preceding write-ahead log file. This is usually the desired behavior for managing write-ahead log archiving behavior, since the preceding file is the last one that currently needs to be archived.

### 9.27.4. Recovery Control Functions

The functions shown in Table 9.88 provide information about the current status of a standby server. These functions may be executed both during recovery and in normal running.

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_is_in_recovery () → boolean</td>
<td>Returns true if recovery is still in progress.</td>
</tr>
<tr>
<td>pg_last_wal_receive_lsn () → pg_lsn</td>
<td>Returns the last write-ahead log location that has been received and synced to disk by streaming replication. While streaming replication is in progress this will increase monotonically. If recovery has completed then this will remain static at the location of the last WAL record received and synced to disk during recovery. If streaming replication is disabled, or if it has not yet started, the function returns NULL.</td>
</tr>
<tr>
<td>pg_last_wal_replay_lsn () → pg_lsn</td>
<td></td>
</tr>
</tbody>
</table>
Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Returns the last write-ahead log location that has been replayed during recovery. If recovery is still in progress this will increase monotonically. If recovery has completed then this will remain static at the location of the last WAL record applied during recovery. When the server has been started normally without recovery, the function returns NULL.</td>
<td></td>
</tr>
</tbody>
</table>

pg_last_xact_replay_timestamp () → timestamp with time zone

Returns the time stamp of the last transaction replayed during recovery. This is the time at which the commit or abort WAL record for that transaction was generated on the primary. If no transactions have been replayed during recovery, the function returns NULL. Otherwise, if recovery is still in progress this will increase monotonically. If recovery has completed then this will remain static at the time of the last transaction applied during recovery. When the server has been started normally without recovery, the function returns NULL.

The functions shown in Table 9.89 control the progress of recovery. These functions may be executed only during recovery.

Table 9.89. Recovery Control Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_is_wal_replay_paused () → boolean</td>
<td></td>
</tr>
<tr>
<td>Returns true if recovery pause is requested.</td>
<td></td>
</tr>
</tbody>
</table>

pg_get_wal_replay_pause_state () → text

Returns recovery pause state. The return values are not paused if pause is not requested, pause requested if pause is requested but recovery is not yet paused, and paused if the recovery is actually paused.

pg_promote (wait boolean DEFAULT true, wait_seconds integer DEFAULT 60) → boolean

Promotes a standby server to primary status. With wait set to true (the default), the function waits until promotion is completed or wait_seconds seconds have passed, and returns true if promotion is successful and false otherwise. If wait is set to false, the function returns true immediately after sending a SIGUSR1 signal to the postmaster to trigger promotion. This function is restricted to superusers by default, but other users can be granted EXECUTE to run the function.

pg_wal_replay_pause () → void

Request to pause recovery. A request doesn't mean that recovery stops right away. If you want a guarantee that recovery is actually paused, you need to check for the recovery pause state returned by pg_get_wal_replay_pause_state(). Note that pg_is_wal_replay_paused() returns whether a request is made. While recovery is paused, no further database changes are applied. If hot standby is active, all new queries will see the same consistent snapshot of the database, and no further query conflicts will be generated until recovery is resumed. This function is restricted to superusers by default, but other users can be granted EXECUTE to run the function.

pg_wal_replay_resume () → void

Restarts recovery if it was paused. This function is restricted to superusers by default, but other users can be granted EXECUTE to run the function.

pg_wal_replay_pause and pg_wal_replay_resume cannot be executed while a promotion is ongoing. If a promotion is triggered while recovery is paused, the paused state ends and promotion continues.

If streaming replication is disabled, the paused state may continue indefinitely without a problem. If streaming replication is in progress then WAL records will continue to be received, which will eventually
fill available disk space, depending upon the duration of the pause, the rate of WAL generation and available disk space.

9.27.5. Snapshot Synchronization Functions

Postgres Pro allows database sessions to synchronize their snapshots. A snapshot determines which data is visible to the transaction that is using the snapshot. Synchronized snapshots are necessary when two or more sessions need to see identical content in the database. If two sessions just start their transactions independently, there is always a possibility that some third transaction commits between the executions of the two START TRANSACTION commands, so that one session sees the effects of that transaction and the other does not.

To solve this problem, Postgres Pro allows a transaction to export the snapshot it is using. As long as the exporting transaction remains open, other transactions can import its snapshot, and thereby be guaranteed that they see exactly the same view of the database that the first transaction sees. But note that any database changes made by any one of these transactions remain invisible to the other transactions, as is usual for changes made by uncommitted transactions. So the transactions are synchronized with respect to pre-existing data, but act normally for changes they make themselves.

Snapshots are exported with the pg_export_snapshot function, shown in Table 9.90, and imported with the SET TRANSACTION command.

Table 9.90. Snapshot Synchronization Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_export_snapshot () → text</td>
<td>Saves the transaction's current snapshot and returns a text string identifying the snapshot. This string must be passed (outside the database) to clients that want to import the snapshot. The snapshot is available for import only until the end of the transaction that exported it. A transaction can export more than one snapshot, if needed. Note that doing so is only useful in READ COMMITTED transactions, since in REPEATABLE READ and higher isolation levels, transactions use the same snapshot throughout their lifetime. Once a transaction has exported any snapshots, it cannot be prepared with PREPARE TRANSACTION.</td>
</tr>
</tbody>
</table>

9.27.6. Replication Management Functions

The functions shown in Table 9.91 are for controlling and interacting with replication features. See Section 25.2.5, Section 25.2.6, and Chapter 48 for information about the underlying features. Use of functions for replication origin is only allowed to the superuser by default, but may be allowed to other users by using the GRANT command. Use of functions for replication slots is restricted to superusers and users having REPLICATION privilege.

Many of these functions have equivalent commands in the replication protocol; see Section 51.4.

The functions described in Section 9.27.3, Section 9.27.4, and Section 9.27.5 are also relevant for replication.

Table 9.91. Replication Management Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_create_physical_replication_slot (slot_name name [, immediately_reserve boolean, temporary boolean ]) → record (slot_name name, lsn pg_lsn)</td>
<td>Creates a new physical replication slot named slot_name. The optional second parameter, when true, specifies that the LSN for this replication slot be reserved immediately; otherwise the LSN is reserved on first connection from a streaming replication client. Streaming changes from a physical slot is only possible with the streaming-replication protocol — see Section 51.4. The optional third parameter, temporary, when set to true, specifies that the slot should not be permanently stored to disk and is only meant for use by the current</td>
</tr>
</tbody>
</table>
### Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pg_drop_replication_slot</code> (slot_name name) → void</td>
<td>Drops the physical or logical replication slot named <code>slot_name</code>. Same as replication protocol command <code>DROP_REPLICATION_SLOT</code>. For logical slots, this must be called while connected to the same database the slot was created on.</td>
</tr>
<tr>
<td><code>pg_create_logical_replication_slot</code> (slot_name name, plugin name [temporary boolean, two_phase boolean]) → record (slot_name name, lsn pg_lsn)</td>
<td>Creates a new logical (decoding) replication slot named <code>slot_name</code> using the output plugin <code>plugin</code>. The optional third parameter, <code>temporary</code>, when set to true, specifies that the slot should not be permanently stored to disk and is only meant for use by the current session. Temporary slots are also released upon any error. The optional fourth parameter, <code>two_phase</code>, when set to true, specifies that the decoding of prepared transactions is enabled for this slot. A call to this function has the same effect as the replication protocol command <code>CREATE_REPLICATION_SLOT</code>.</td>
</tr>
<tr>
<td><code>pg_copy_physical_replication_slot</code> (src_slot_name name, dst_slot_name name [temporary boolean]) → record (slot_name name, lsn pg_lsn)</td>
<td>Copies an existing physical replication slot named <code>src_slot_name</code> to a physical replication slot named <code>dst_slot_name</code>. The copied physical slot starts to reserve WAL from the same LSN as the source slot. <code>temporary</code> is optional. If <code>temporary</code> is omitted, the same value as the source slot is used.</td>
</tr>
<tr>
<td><code>pg_copy_logical_replication_slot</code> (src_slot_name name, dst_slot_name name [temporary boolean, plugin name]) → record (slot_name name, lsn pg_lsn)</td>
<td>Copies an existing logical replication slot named <code>src_slot_name</code> to a logical replication slot named <code>dst_slot_name</code>, optionally changing the output plugin and persistence. The copied logical slot starts from the same LSN as the source logical slot. Both <code>temporary</code> and <code>plugin</code> are optional; if they are omitted, the values of the source slot are used.</td>
</tr>
<tr>
<td><code>pg_logical_slot_get_changes</code> (slot_name name, upto_lsn pg_lsn, upto_nchanges integer, VARIADIC options text[]) → setof record (lsn pg_lsn, xid xid, data text)</td>
<td>Returns changes in the slot <code>slot_name</code>, starting from the point from which changes have been consumed last. If <code>upto_lsn</code> and <code>upto_nchanges</code> are NULL, logical decoding will continue until end of WAL. If <code>upto_lsn</code> is non-NULL, decoding will include only those transactions which commit prior to the specified LSN. If <code>upto_nchanges</code> is non-NULL, decoding will stop when the number of rows produced by decoding exceeds the specified value. Note, however, that the actual number of rows returned may be larger, since this limit is only checked after adding the rows produced when decoding each new transaction commit.</td>
</tr>
<tr>
<td><code>pg_logical_slot.peek_changes</code> (slot_name name, upto_lsn pg_lsn, upto_nchanges integer, VARIADIC options text[]) → setof record (lsn pg_lsn, xid xid, data bytea)</td>
<td>Behaves just like the <code>pg_logical_slot.get_changes()</code> function, except that changes are not consumed; that is, they will be returned again on future calls.</td>
</tr>
<tr>
<td><code>pg_logical_slot.get_binary_changes</code> (slot_name name, upto_lsn pg_lsn, upto_nchanges integer, VARIADIC options text[]) → setof record (lsn pg_lsn, xid xid, data bytea)</td>
<td>Behaves just like the <code>pg_logical_slot.get_changes()</code> function, except that changes are returned as bytea.</td>
</tr>
<tr>
<td><code>pg_logical_slot.peek_binary_changes</code> (slot_name name, upto_lsn pg_lsn, upto_nchanges integer, VARIADIC options text[]) → setof record (lsn pg_lsn, xid xid, data bytea)</td>
<td>Behaves just like the <code>pg_logical_slot.peek_changes()</code> function, except that changes are returned as bytea.</td>
</tr>
</tbody>
</table>
## Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Behaves just like the pg_logical_slot_peek_changes() function, except that changes are returned as bytea.</strong></td>
<td></td>
</tr>
</tbody>
</table>

```sql
pg_replication_slot_advance ( slot_name name, upto_lsn pg_lsn ) → record ( slot_name name, end_lsn pg_lsn )
```

Advances the current confirmed position of a replication slot named `slot_name`. The slot will not be moved backwards, and it will not be moved beyond the current insert location. Returns the name of the slot and the actual position that it was advanced to. The updated slot position information is written out at the next checkpoint if any advancing is done. So in the event of a crash, the slot may return to an earlier position.

```sql
pg_replication_origin_create ( node_name text ) → oid
```

Creates a replication origin with the given external name, and returns the internal ID assigned to it.

```sql
pg_replication_origin_drop ( node_name text ) → void
```

Deletes a previously-created replication origin, including any associated replay progress.

```sql
pg_replication_origin_oid ( node_name text ) → oid
```

Looks up a replication origin by name and returns the internal ID. If no such replication origin is found an error is thrown.

```sql
pg_replication_origin_session_setup ( node_name text ) → void
```

Marks the current session as replaying from the given origin, allowing replay progress to be tracked. Can only be used if no origin is currently selected. Use `pg_replication_origin_session_reset` to undo.

```sql
pg_replication_origin_session_reset () → void
```

Cancels the effects of `pg_replication_origin_session_setup()`.

```sql
pg_replication_origin_session_is_setup () → boolean
```

Returns true if a replication origin has been selected in the current session.

```sql
pg_replication_origin_session_progress ( flush boolean ) → pg_lsn
```

Returns the replay location for the replication origin selected in the current session. The parameter `flush` determines whether the corresponding local transaction will be guaranteed to have been flushed to disk or not.

```sql
pg_replication_origin_xact_setup ( origin_lsn pg_lsn, origin_timestamp timestamp with time zone ) → void
```

Marks the current transaction as replaying a transaction that has committed at the given LSN and timestamp. Can only be called when a replication origin has been selected using `pg_replication_origin_session_setup`.

```sql
pg_replication_origin_xact_reset () → void
```

Cancels the effects of `pg_replication_origin_xact_setup()`.

```sql
pg_replication_origin_advance ( node_name text, lsn pg_lsn ) → void
```

Sets replication progress for the given node to the given location. This is primarily useful for setting up the initial location, or setting a new location after configuration changes and similar. Be aware that careless use of this function can lead to inconsistently replicated data.

```sql
pg_replication_origin_progress ( node_name text, flush boolean ) → pg_lsn
```

Returns the replay location for the given replication origin. The parameter `flush` determines whether the corresponding local transaction will be guaranteed to have been flushed to disk or not.

```sql
pg_logical_emit_message ( transactional boolean, prefix text, content text ) → pg_lsn
```

```sql
pg_logical_emit_message ( transactional boolean, prefix text, content bytea ) → pg_lsn
```
### 9.27.7. Database Object Management Functions

The functions shown in Table 9.92 calculate the disk space usage of database objects, or assist in presentation or understanding of usage results. bigint results are measured in bytes. If an OID that does not represent an existing object is passed to one of these functions, NULL is returned.

**Table 9.92. Database Object Size Functions**

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pg_column_size</code></td>
<td>(&quot;any&quot;)\rightarrow integer</td>
</tr>
<tr>
<td><code>pg_column_compression</code></td>
<td>(&quot;any&quot;)\rightarrow text</td>
</tr>
<tr>
<td><code>pg_database_size</code></td>
<td>(name)\rightarrow bigint</td>
</tr>
<tr>
<td><code>pg_database_size</code></td>
<td>(oid)\rightarrow bigint</td>
</tr>
<tr>
<td><code>pg_indexes_size</code></td>
<td>(regclass)\rightarrow bigint</td>
</tr>
<tr>
<td><code>pg_relation_size</code></td>
<td>(relation regclass[, fork text ] )\rightarrow bigint</td>
</tr>
<tr>
<td><code>pg_size_bytes</code></td>
<td>(text)\rightarrow bigint</td>
</tr>
<tr>
<td><code>pg_size_pretty</code></td>
<td>(bigint)\rightarrow text</td>
</tr>
<tr>
<td><code>pg_size_pretty</code></td>
<td>(numeric)\rightarrow text</td>
</tr>
<tr>
<td><code>pg_table_size</code></td>
<td>(regclass)\rightarrow bigint</td>
</tr>
</tbody>
</table>

**Function Description**

- **Emits a logical decoding message.** This can be used to pass generic messages to logical decoding plugins through WAL. The `transactional` parameter specifies if the message should be part of the current transaction, or if it should be written immediately and decoded as soon as the logical decoder reads the record. The `prefix` parameter is a textual prefix that can be used by logical decoding plugins to easily recognize messages that are interesting for them. The `content` parameter is the content of the message, given either in text or binary form.
Functions and Operators

### Function Description

- **pg_tablespace_size (name)** → bigint
  - Computes the disk space used by the specified table, excluding indexes (but including its TOAST table if any, free space map, and visibility map).

- **pg_tablespace_size (oid)** → bigint
  - Computes the total disk space used in the tablespace with the specified name or OID. To use this function, you must have CREATE privilege on the specified tablespace or be a member of the pg_read_all_stats role, unless it is the default tablespace for the current database.

- **pg_total_relation_size (regclass)** → bigint
  - Computes the total disk space used by the specified table, including all indexes and TOAST data. The result is equivalent to `pg_table_size + pg_indexes_size`.

The functions above that operate on tables or indexes accept a *regclass* argument, which is simply the OID of the table or index in the *pg_class* system catalog. You do not have to look up the OID by hand, however, since the *regclass* data type's input converter will do the work for you. See Section 8.19 for details.

The functions shown in Table 9.93 assist in identifying the specific disk files associated with database objects.

### Table 9.93. Database Object Location Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>pg_relation_filenode (relation regclass)</strong> → oid</td>
<td>Returns the “filenode” number currently assigned to the specified relation. The filenode is the base component of the file name(s) used for the relation (see Section 66.1 for more information). For most relations the result is the same as <em>pg_class</em>.relfilenode, but for certain system catalogs relfilenode is zero and this function must be used to get the correct value. The function returns NULL if passed a relation that does not have storage, such as a view.</td>
</tr>
<tr>
<td><strong>pg_relation_filepath (relation regclass)</strong> → text</td>
<td>Returns the entire file path name (relative to the database cluster's data directory, <em>PGDATA</em>) of the relation.</td>
</tr>
<tr>
<td><strong>pg_filenode_relation (tablespace oid, filenode oid)</strong> → regclass</td>
<td>Returns a relation's OID given the tablespace OID and filenode it is stored under. This is essentially the inverse mapping of <em>pg_relation_filepath</em>. For a relation in the database's default tablespace, the tablespace can be specified as zero. Returns NULL if no relation in the current database is associated with the given values.</td>
</tr>
</tbody>
</table>

### Table 9.94 lists functions used to manage collations.

### Table 9.94. Collation Management Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>pg_collation_actual_version (oid)</strong> → text</td>
<td>Returns the actual version of the collation object as it is currently installed in the operating system. If this is different from the value in <em>pg_collation</em>.collversion, then objects depending on the collation might need to be rebuilt. See also <em>ALTER COLLATION</em>.</td>
</tr>
<tr>
<td><strong>pg_import_system_collations (schema regnamespace)</strong> → integer</td>
<td></td>
</tr>
</tbody>
</table>
**Function**

**Description**

Adds collations to the system catalog `pg_collation` based on all the locales it finds in the operating system. This is what `initdb` uses; see Section 22.2.2 for more details. If additional locales are installed into the operating system later on, this function can be run again to add collations for the new locales. Locales that match existing entries in `pg_collation` will be skipped. (But collation objects based on locales that are no longer present in the operating system are not removed by this function.) The `schema` parameter would typically be `pg_catalog`, but that is not a requirement; the collations could be installed into some other schema as well. The function returns the number of new collation objects it created. Use of this function is restricted to superusers.

Table 9.95 lists functions that provide information about the structure of partitioned tables.

### Table 9.95. Partitioning Information Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pg_partition_tree</code> (regclass) → setof record</td>
<td>Lists the tables or indexes in the partition tree of the given partitioned table or partitioned index, with one row for each partition. Information provided includes the OID of the partition, the OID of its immediate parent, a boolean value telling if the partition is a leaf, and an integer telling its level in the hierarchy. The level value is 0 for the input table or index, 1 for its immediate child partitions, 2 for their partitions, and so on. Returns no rows if the relation does not exist or is not a partition or partitioned table.</td>
</tr>
<tr>
<td><code>pg_partition_ancestors</code> (regclass) → setof regclass</td>
<td>Lists the ancestor relations of the given partition, including the relation itself. Returns no rows if the relation does not exist or is not a partition or partitioned table.</td>
</tr>
<tr>
<td><code>pg_partition_root</code> (regclass) → regclass</td>
<td>Returns the top-most parent of the partition tree to which the given relation belongs. Returns NULL if the relation does not exist or is not a partition or partitioned table.</td>
</tr>
</tbody>
</table>

For example, to check the total size of the data contained in a partitioned table `measurement`, one could use the following query:

```sql
SELECT pg_size_pretty(sum(pg_relation_size(relid))) AS total_size
FROM pg_partition_tree('measurement');
```

### 9.27.8. Index Maintenance Functions

Table 9.96 shows the functions available for index maintenance tasks. (Note that these maintenance tasks are normally done automatically by autovacuum; use of these functions is only required in special cases.) These functions cannot be executed during recovery. Use of these functions is restricted to superusers and the owner of the given index.

### Table 9.96. Index Maintenance Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>brin_summarize_new_values</code> (index regclass) → integer</td>
<td>Scans the specified BRIN index to find page ranges in the base table that are not currently summarized by the index; for any such range it creates a new summary index tuple by scanning those table pages. Returns the number of new page range summaries that were inserted into the index.</td>
</tr>
<tr>
<td><code>brin_summarize_range</code> (index regclass, blockNumber bigint) → integer</td>
<td></td>
</tr>
</tbody>
</table>
### Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>brin_desummarize_range</strong></td>
<td>(index regclass, blockNumber bigint) → void&lt;br&gt;Removes the BRIN index tuple that summarizes the page range covering the given table block, if there is one.</td>
</tr>
<tr>
<td><strong>gin_clean_pending_list</strong></td>
<td>(index regclass) → bigint&lt;br&gt;Cleans up the “pending” list of the specified GIN index by moving entries in it, in bulk, to the main GIN data structure. Returns the number of pages removed from the pending list. If the argument is a GIN index built with the fastupdate option disabled, no cleanup happens and the result is zero, because the index doesn’t have a pending list. See Section 63.4.1 and Section 63.5 for details about the pending list and fastupdate option.</td>
</tr>
</tbody>
</table>

### 9.27.9. Generic File Access Functions

The functions shown in Table 9.97 provide native access to files on the machine hosting the server. Only files within the database cluster directory and the log_directory can be accessed, unless the user is a superuser or is granted the role pg_read_server_files. Use a relative path for files in the cluster directory, and a path matching the log_directory configuration setting for log files.

Note that granting users the EXECUTE privilege on pg_read_file(), or related functions, allows them the ability to read any file on the server that the database server process can read; these functions bypass all in-database privilege checks. This means that, for example, a user with such access is able to read the contents of the pg_authid table where authentication information is stored, as well as read any table data in the database. Therefore, granting access to these functions should be carefully considered.

Some of these functions take an optional missing_ok parameter, which specifies the behavior when the file or directory does not exist. If true, the function returns NULL or an empty result set, as appropriate. If false, an error is raised. The default is false.

#### Table 9.97. Generic File Access Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>pg_ls_dir</strong></td>
<td>(dirname text [, missing_ok boolean, include_dot_dirs boolean ]) → setof text&lt;br&gt;Returns the names of all files (and directories and other special files) in the specified directory. The include_dot_dirs parameter indicates whether “.” and “..” are to be included in the result set; the default is to exclude them. Including them can be useful when missing_ok is true, to distinguish an empty directory from a non-existent directory. This function is restricted to superusers by default, but other users can be granted EXECUTE to run the function.</td>
</tr>
<tr>
<td><strong>pg_ls_logdir</strong></td>
<td>() → setof record (name text, size bigint, modification timestamp with timezone) &lt;br&gt;Returns the name, size, and last modification time (mtime) of each ordinary file in the server's log directory. Filenames beginning with a dot, directories, and other special files are excluded. This function is restricted to superusers and members of the pg_monitor role by default, but other users can be granted EXECUTE to run the function.</td>
</tr>
<tr>
<td><strong>pg_ls_waldir</strong></td>
<td>() → setof record (name text, size bigint, modification timestamp with timezone) &lt;br&gt;Returns the name, size, and last modification time (mtime) of each ordinary file in the server's write-ahead log (WAL) directory. Filenames beginning with a dot, directories, and other special files are excluded.</td>
</tr>
<tr>
<td>Function</td>
<td>Description</td>
</tr>
<tr>
<td>----------------------------------</td>
<td>---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>pg_ls_archive_statusdir</td>
<td>Returns the name, size, and last modification time (mtime) of each ordinary file in the server's WAL archive status directory (pg_wal/archive_status). Filenames beginning with a dot, directories, and other special files are excluded. This function is restricted to superusers and members of the <code>pg_monitor</code> role by default, but other users can be granted EXECUTE to run the function.</td>
</tr>
<tr>
<td>pg_ls_tmpdir</td>
<td>Returns the name, size, and last modification time (mtime) of each ordinary file in the temporary file directory for the specified <code>tablespace</code>. If <code>tablespace</code> is not provided, the <code>pg_default</code> tablespace is examined. Filenames beginning with a dot, directories, and other special files are excluded. This function is restricted to superusers and members of the <code>pg_monitor</code> role by default, but other users can be granted EXECUTE to run the function.</td>
</tr>
<tr>
<td>pg_read_file</td>
<td>Returns all or part of a text file, starting at the given byte <code>offset</code>, returning at most <code>length</code> bytes (less if the end of file is reached first). If <code>offset</code> is negative, it is relative to the end of the file. If <code>offset</code> and <code>length</code> are omitted, the entire file is returned. The bytes read from the file are interpreted as a string in the database's encoding; an error is thrown if they are not valid in that encoding. This function is restricted to superusers by default, but other users can be granted EXECUTE to run the function.</td>
</tr>
</tbody>
</table>
| pg_read_binary_file              | Returns all or part of a file. This function is identical to `pg_read_file` except that it can read arbitrary binary data, returning the result as `bytea` not `text`; accordingly, no encoding checks are performed. This function is restricted to superusers by default, but other users can be granted EXECUTE to run the function. The function can be used to read a text file in a specified encoding and convert to the database's encoding:  
  ```sql
  SELECT convert_from(pg_read_binary_file('file_in_utf8.txt'), 'UTF8');
  ```  |
| pg_stat_file                     | Returns a record containing the file's size, last access time stamp, last modification time stamp, last file status change time stamp (Unix platforms only), file creation time stamp (Windows only), and a flag indicating if it is a directory. This function is restricted to superusers by default, but other users can be granted EXECUTE to run the function. |

### 9.27.10. Advisory Lock Functions

The functions shown in Table 9.98 manage advisory locks. For details about proper use of these functions, see Section 13.3.5.

All these functions are intended to be used to lock application-defined resources, which can be identified either by a single 64-bit key value or two 32-bit key values (note that these two key spaces do not
If another session already holds a conflicting lock on the same resource identifier, the functions will either wait until the resource becomes available, or return a \texttt{false} result, as appropriate for the function. Locks can be either shared or exclusive: a shared lock does not conflict with other shared locks on the same resource, only with exclusive locks. Locks can be taken at session level (so that they are held until released or the session ends) or at transaction level (so that they are held until the current transaction ends; there is no provision for manual release). Multiple session-level lock requests stack, so that if the same resource identifier is locked three times there must then be three unlock requests to release the resource in advance of session end.

### Table 9.98. Advisory Lock Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{pg_advisory_lock} ( (\text{key bigint}) \rightarrow \text{void} )</td>
<td>Obtains an exclusive session-level advisory lock, waiting if necessary.</td>
</tr>
<tr>
<td>\texttt{pg_advisory_lock} ( (\text{key1 integer, key2 integer}) \rightarrow \text{void} )</td>
<td></td>
</tr>
<tr>
<td>\texttt{pg_advisory_lock_shared} ( (\text{key bigint}) \rightarrow \text{void} )</td>
<td>Obtains a shared session-level advisory lock, waiting if necessary.</td>
</tr>
<tr>
<td>\texttt{pg_advisory_lock_shared} ( (\text{key1 integer, key2 integer}) \rightarrow \text{void} )</td>
<td></td>
</tr>
<tr>
<td>\texttt{pg_advisory_unlock} ( (\text{key bigint}) \rightarrow \text{boolean} )</td>
<td>Releases a previously-acquired exclusive session-level advisory lock. Returns \texttt{true} if the lock is successfully released. If the lock was not held, \texttt{false} is returned, and in addition, an SQL warning will be reported by the server.</td>
</tr>
<tr>
<td>\texttt{pg_advisory_unlock} ( (\text{key1 integer, key2 integer}) \rightarrow \text{boolean} )</td>
<td></td>
</tr>
<tr>
<td>\texttt{pg_advisory_unlock_all} ( () \rightarrow \text{void} )</td>
<td>Releases all session-level advisory locks held by the current session. (This function is implicitly invoked at session end, even if the client disconnects ungracefully.)</td>
</tr>
<tr>
<td>\texttt{pg_advisory_unlock_shared} ( (\text{key bigint}) \rightarrow \text{boolean} )</td>
<td></td>
</tr>
<tr>
<td>\texttt{pg_advisory_unlock_shared} ( (\text{key1 integer, key2 integer}) \rightarrow \text{boolean} )</td>
<td></td>
</tr>
<tr>
<td>\texttt{pg_advisory_xact_lock} ( (\text{key bigint}) \rightarrow \text{void} )</td>
<td>Obtains an exclusive transaction-level advisory lock, waiting if necessary.</td>
</tr>
<tr>
<td>\texttt{pg_advisory_xact_lock} ( (\text{key1 integer, key2 integer}) \rightarrow \text{void} )</td>
<td></td>
</tr>
<tr>
<td>\texttt{pg_advisory_xact_lock_shared} ( (\text{key bigint}) \rightarrow \text{void} )</td>
<td>Obtains a shared transaction-level advisory lock, waiting if necessary.</td>
</tr>
<tr>
<td>\texttt{pg_advisory_xact_lock_shared} ( (\text{key1 integer, key2 integer}) \rightarrow \text{void} )</td>
<td></td>
</tr>
<tr>
<td>\texttt{pg_try_advisory_lock} ( (\text{key bigint}) \rightarrow \text{boolean} )</td>
<td>Obtains an exclusive session-level advisory lock if available. This will either obtain the lock immediately and return \texttt{true}, or return \texttt{false} without waiting if the lock cannot be acquired immediately.</td>
</tr>
<tr>
<td>\texttt{pg_try_advisory_lock} ( (\text{key1 integer, key2 integer}) \rightarrow \text{boolean} )</td>
<td></td>
</tr>
<tr>
<td>\texttt{pg_try_advisory_lock_shared} ( (\text{key bigint}) \rightarrow \text{boolean} )</td>
<td>Obtains a shared session-level advisory lock if available. This will either obtain the lock immediately and return \texttt{true}, or return \texttt{false} without waiting if the lock cannot be acquired immediately.</td>
</tr>
<tr>
<td>\texttt{pg_try_advisory_lock_shared} ( (\text{key1 integer, key2 integer}) \rightarrow \text{boolean} )</td>
<td></td>
</tr>
<tr>
<td>\texttt{pg_try_advisory_xact_lock} ( (\text{key bigint}) \rightarrow \text{boolean} )</td>
<td></td>
</tr>
<tr>
<td>\texttt{pg_try_advisory_xact_lock} ( (\text{key1 integer, key2 integer}) \rightarrow \text{boolean} )</td>
<td></td>
</tr>
</tbody>
</table>

345
<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_try_advisory_xact_lock_shared</td>
<td>Obtains an exclusive transaction-level advisory lock if available. This will either obtain the lock immediately and return true, or return false without waiting if the lock cannot be acquired immediately.</td>
</tr>
<tr>
<td>pg_try_advisory_xact_lock_shared</td>
<td>Obtains a shared transaction-level advisory lock if available. This will either obtain the lock immediately and return true, or return false without waiting if the lock cannot be acquired immediately.</td>

</tbody>
</table>

### 9.27.11. Debugging Functions

The function shown in Table 9.99 can assist you in low-level activities, such as debugging or exploring corrupted Postgres Pro databases.

**Table 9.99. Snapshot Synchronization Functions**

<table>
<thead>
<tr>
<th>Name</th>
<th>Return Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_snapshot_any()</td>
<td>void</td>
<td>Sets the current transaction to ignore MVCC rules and see all versions of data.</td>
</tr>
</tbody>
</table>

Use `pg_snapshot_any` with care. Run it in a transaction with isolation level `REPEATABLE READ` or higher, otherwise the specific snapshot will be replaced by a new one by the next query. Only superusers can run this function.

**Note**

If you created the database cluster using the server version that did not provide this function, execute the command:

```
CREATE FUNCTION pg_snapshot_any() RETURNS void AS 'pg_snapshot_any' LANGUAGE internal;
```

### 9.28. Trigger Functions

While many uses of triggers involve user-written trigger functions, PostgreSQL provides a few built-in trigger functions that can be used directly in user-defined triggers. These are summarized in Table 9.100. (Additional built-in trigger functions exist, which implement foreign key constraints and deferred index constraints. Those are not documented here since users need not use them directly.)

For more information about creating triggers, see CREATE TRIGGER.

**Table 9.100. Built-In Trigger Functions**

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>suppress_redundant_updates_trigger</td>
<td>Suppresses do-nothing update operations. See below for details.</td>
</tr>
<tr>
<td>tsvector_update_trigger</td>
<td>Automatically updates a tsvector column from associated plain-text document column(s). The text search configuration to use is specified by name as a trigger argument. See Section 12.4.3 for details.</td>
</tr>
</tbody>
</table>

For more information about creating triggers, see CREATE TRIGGER.
Functions and Operators

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
<th>Example Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td>CREATE TRIGGER ... tsvector_update_trigger(tsvcol, 'pg_catalog.swedish', title, body)</td>
<td>Automatically updates a tsvector column from associated plain-text document column(s). The text search configuration to use is taken from a regconfig column of the table. See Section 12.4.3 for details.</td>
<td></td>
</tr>
</tbody>
</table>

The `tsvector_update_trigger_column` function, when applied as a row-level BEFORE UPDATE trigger, will prevent any update that does not actually change the data in the row from taking place. This overrides the normal behavior which always performs a physical row update regardless of whether or not the data has changed. (This normal behavior makes updates run faster, since no checking is required, and is also useful in certain cases.)

Ideally, you should avoid running updates that don't actually change the data in the record. Redundant updates can cost considerable unnecessary time, especially if there are lots of indexes to alter, and space in dead rows that will eventually have to be vacuumed. However, detecting such situations in client code is not always easy, or even possible, and writing expressions to detect them can be error-prone. An alternative is to use `suppress_redundant_updates_trigger`, which will skip updates that don't change the data. You should use this with care, however. The trigger takes a small but non-trivial time for each record, so if most of the records affected by updates do actually change, use of this trigger will make updates run slower on average.

The `suppress_redundant_updates_trigger` function can be added to a table like this:

```
CREATE TRIGGER z_min_update
BEFORE UPDATE ON tablename
FOR EACH ROW EXECUTE FUNCTION suppress_redundant_updates_trigger();
```

In most cases, you need to fire this trigger last for each row, so that it does not override other triggers that might wish to alter the row. Bearing in mind that triggers fire in name order, you would therefore choose a trigger name that comes after the name of any other trigger you might have on the table. (Hence the “z” prefix in the example.)

9.29. Event Trigger Functions

Postgres Pro provides these helper functions to retrieve information from event triggers.

For more information about event triggers, see Chapter 38.

9.29.1. Capturing Changes at Command End

`pg_event_trigger_ddl_commands` function returns a list of DDL commands executed by each user action, when invoked in a function attached to a `ddl_command_end` event trigger. If called in any other context, an error is raised. `pg_event_trigger_ddl_commands` returns one row for each base command executed; some commands that are a single SQL sentence may return more than one row. This function returns the following columns:

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>classid</td>
<td>oid</td>
<td>OID of catalog the object belongs in</td>
</tr>
<tr>
<td>objid</td>
<td>oid</td>
<td>OID of the object itself</td>
</tr>
</tbody>
</table>
### Functions and Operators

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>objsubid</td>
<td>integer</td>
<td>Sub-object ID (e.g., attribute number for a column)</td>
</tr>
<tr>
<td>command_tag</td>
<td>text</td>
<td>Command tag</td>
</tr>
<tr>
<td>object_type</td>
<td>text</td>
<td>Type of the object</td>
</tr>
<tr>
<td>schema_name</td>
<td>text</td>
<td>Name of the schema the object belongs in, if any; otherwise NULL. No quoting is applied.</td>
</tr>
<tr>
<td>object_identity</td>
<td>text</td>
<td>Text rendering of the object identity, schema-qualified. Each identifier included in the identity is quoted if necessary.</td>
</tr>
<tr>
<td>in_extension</td>
<td>boolean</td>
<td>True if the command is part of an extension script</td>
</tr>
<tr>
<td>command</td>
<td>pg_ddl_command</td>
<td>A complete representation of the command, in internal format. This cannot be output directly, but it can be passed to other functions to obtain different pieces of information about the command.</td>
</tr>
</tbody>
</table>

#### 9.29.2. Processing Objects Dropped by a DDL Command

`pg_event_trigger_dropped_objects () → setof record`

`pg_event_trigger_dropped_objects` returns a list of all objects dropped by the command in whose `sql_drop` event it is called. If called in any other context, an error is raised. This function returns the following columns:

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>classid</td>
<td>oid</td>
<td>OID of catalog the object belonged in</td>
</tr>
<tr>
<td>objid</td>
<td>oid</td>
<td>OID of the object itself</td>
</tr>
<tr>
<td>objsubid</td>
<td>integer</td>
<td>Sub-object ID (e.g., attribute number for a column)</td>
</tr>
<tr>
<td>original</td>
<td>boolean</td>
<td>True if this was one of the root object(s) of the deletion</td>
</tr>
<tr>
<td>normal</td>
<td>boolean</td>
<td>True if there was a normal dependency relationship in the dependency graph leading to this object</td>
</tr>
<tr>
<td>is_temporary</td>
<td>boolean</td>
<td>True if this was a temporary object</td>
</tr>
<tr>
<td>object_type</td>
<td>text</td>
<td>Type of the object</td>
</tr>
<tr>
<td>schema_name</td>
<td>text</td>
<td>Name of the schema the object belonged in, if any; otherwise NULL. No quoting is applied.</td>
</tr>
<tr>
<td>object_name</td>
<td>text</td>
<td>Name of the object, if the combination of schema and name can be used as a unique identifier for the object;</td>
</tr>
</tbody>
</table>
Functions and Operators

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>object_identity</td>
<td>text</td>
<td>Text rendering of the object identity, schema-qualified. Each identifier included in the identity is quoted if necessary.</td>
</tr>
<tr>
<td>address_names</td>
<td>text[]</td>
<td>An array that, together with object_type and address_args, can be used by the pg_get_object_address function to recreate the object address in a remote server containing an identically named object of the same kind.</td>
</tr>
<tr>
<td>address_args</td>
<td>text[]</td>
<td>Complement for address_names.</td>
</tr>
</tbody>
</table>

The `pg_event_trigger_dropped_objects` function can be used in an event trigger like this:

```sql
CREATE FUNCTION test_event_trigger_for_drops()
RETURNS event_trigger LANGUAGE plpgsql AS $$
DECLARE
  obj record;
BEGIN
  FOR obj IN SELECT * FROM pg_event_trigger_dropped_objects()
  LOOP
    RAISE NOTICE '% dropped object: % %.% %',
    tg_tag,
    obj.object_type,
    obj.schema_name,
    obj.object_name,
    obj.object_identity;
  END LOOP;
END;
$$;
CREATE EVENT TRIGGER test_event_trigger_for_drops
ON sql_drop
EXECUTE FUNCTION test_event_trigger_for_drops();
```

### 9.29.3. Handling a Table Rewrite Event

The functions shown in Table 9.101 provide information about a table for which a `table_rewrite` event has just been called. If called in any other context, an error is raised.

#### Table 9.101. Table Rewrite Information Functions

<table>
<thead>
<tr>
<th>Function</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_event_trigger_table_rewrite_oid() → oid</td>
<td>Returns the OID of the table about to be rewritten.</td>
</tr>
<tr>
<td>pg_event_trigger_table_rewrite_reason() → integer</td>
<td>Returns a code explaining the reason(s) for rewriting. The exact meaning of the codes is release dependent.</td>
</tr>
</tbody>
</table>

These functions can be used in an event trigger like this:
CREATE FUNCTION test_event_trigger_table_rewrite_oid()
RETURNS event_trigger
LANGUAGE plpgsql AS
$$
BEGIN
   RAISE NOTICE 'rewriting table % for reason %',
   pg_event_trigger_table_rewrite_oid()::regclass,
   pg_event_trigger_table_rewrite_reason();
END;
$$;

CREATE EVENT TRIGGER test_table_rewrite_oid
ON table_rewrite
   EXECUTE FUNCTION test_event_trigger_table_rewrite_oid();

9.30. Statistics Information Functions

Postgres Pro provides a function to inspect complex statistics defined using the CREATE STATISTICS command.

9.30.1. Inspecting MCV Lists

pg_mcv_list_items ( pg_mcv_list ) → setof record

pg_mcv_list_items returns a set of records describing all items stored in a multi-column MCV list. It returns the following columns:

<table>
<thead>
<tr>
<th>Name</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>index</td>
<td>integer</td>
<td>index of the item in the MCV list</td>
</tr>
<tr>
<td>values</td>
<td>text[]</td>
<td>values stored in the MCV item</td>
</tr>
<tr>
<td>nulls</td>
<td>boolean[]</td>
<td>flags identifying NULL values</td>
</tr>
<tr>
<td>frequency</td>
<td>double precision</td>
<td>frequency of this MCV item</td>
</tr>
<tr>
<td>base_frequency</td>
<td>double precision</td>
<td>base frequency of this MCV item</td>
</tr>
</tbody>
</table>

The pg_mcv_list_items function can be used like this:

SELECT m.* FROM pg_statistic_ext join pg_statistic_ext_data on (oid = stxoid),
   pg_mcv_list_items(stxdmcv) m WHERE stxname = 'stts';

Values of the pg_mcv_list type can be obtained only from the pg_statistic_ext_data.stxdmcv column.
Chapter 10. Type Conversion

SQL statements can, intentionally or not, require the mixing of different data types in the same expression. Postgres Pro has extensive facilities for evaluating mixed-type expressions.

In many cases a user does not need to understand the details of the type conversion mechanism. However, implicit conversions done by Postgres Pro can affect the results of a query. When necessary, these results can be tailored by using explicit type conversion.

This chapter introduces the Postgres Pro type conversion mechanisms and conventions. Refer to the relevant sections in Chapter 8 and Chapter 9 for more information on specific data types and allowed functions and operators.

10.1. Overview

SQL is a strongly typed language. That is, every data item has an associated data type which determines its behavior and allowed usage. Postgres Pro has an extensible type system that is more general and flexible than other SQL implementations. Hence, most type conversion behavior in Postgres Pro is governed by general rules rather than by ad hoc heuristics. This allows the use of mixed-type expressions even with user-defined types.

The Postgres Pro scanner/parser divides lexical elements into five fundamental categories: integers, non-integer numbers, strings, identifiers, and key words. Constants of most non-numeric types are first classified as strings. The SQL language definition allows specifying type names with strings, and this mechanism can be used in Postgres Pro to start the parser down the correct path. For example, the query:

```sql
SELECT text 'Origin' AS "label", point '(0,0)' AS "value";
```

<table>
<thead>
<tr>
<th>label</th>
<th>value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Origin</td>
<td>(0,0)</td>
</tr>
<tr>
<td>(1 row)</td>
<td></td>
</tr>
</tbody>
</table>

has two literal constants, of type `text` and `point`. If a type is not specified for a string literal, then the placeholder type `unknown` is assigned initially, to be resolved in later stages as described below.

There are four fundamental SQL constructs requiring distinct type conversion rules in the Postgres Pro parser:

Function calls

Much of the Postgres Pro type system is built around a rich set of functions. Functions can have one or more arguments. Since Postgres Pro permits function overloading, the function name alone does not uniquely identify the function to be called; the parser must select the right function based on the data types of the supplied arguments.

Operators

Postgres Pro allows expressions with prefix (one-argument) operators, as well as infix (two-argument) operators. Like functions, operators can be overloaded, so the same problem of selecting the right operator exists.

Value Storage

SQL `INSERT` and `UPDATE` statements place the results of expressions into a table. The expressions in the statement must be matched up with, and perhaps converted to, the types of the target columns.

`UNION`, `CASE`, and related constructs

Since all query results from a unionized `SELECT` statement must appear in a single set of columns, the types of the results of each `SELECT` clause must be matched up and converted to a uniform set. Similarly, the result expressions of a `CASE` construct must be converted to a common type so that the `CASE` expression as a whole has a known output type. Some other constructs, such as `ARRAY[]`
and the GREATEST and LEAST functions, likewise require determination of a common type for several subexpressions.

The system catalogs store information about which conversions, or casts, exist between which data types, and how to perform those conversions. Additional casts can be added by the user with the CREATE CAST command. (This is usually done in conjunction with defining new data types. The set of casts between built-in types has been carefully crafted and is best not altered.)

An additional heuristic provided by the parser allows improved determination of the proper casting behavior among groups of types that have implicit casts. Data types are divided into several basic type categories, including boolean, numeric, string, bitstring, datetime, timespan, geometric, network, and user-defined. (For a list see Table 50.65; but note it is also possible to create custom type categories.) Within each category there can be one or more preferred types, which are preferred when there is a choice of possible types. With careful selection of preferred types and available implicit casts, it is possible to ensure that ambiguous expressions (those with multiple candidate parsing solutions) can be resolved in a useful way.

All type conversion rules are designed with several principles in mind:

- Implicit conversions should never have surprising or unpredictable outcomes.
- There should be no extra overhead in the parser or executor if a query does not need implicit type conversion. That is, if a query is well-formed and the types already match, then the query should execute without spending extra time in the parser and without introducing unnecessary implicit conversion calls in the query.
- Additionally, if a query usually requires an implicit conversion for a function, and if then the user defines a new function with the correct argument types, the parser should use this new function and no longer do implicit conversion to use the old function.

### 10.2. Operators

The specific operator that is referenced by an operator expression is determined using the following procedure. Note that this procedure is indirectly affected by the precedence of the operators involved, since that will determine which sub-expressions are taken to be the inputs of which operators. See Section 4.1.6 for more information.

**Operator Type Resolution**

1. Select the operators to be considered from the pg_operator system catalog. If a non-schema-qualified operator name was used (the usual case), the operators considered are those with the matching name and argument count that are visible in the current search path (see Section 5.9.3). If a qualified operator name was given, only operators in the specified schema are considered.

   • (Optional) If the search path finds multiple operators with identical argument types, only the one appearing earliest in the path is considered. Operators with different argument types are considered on an equal footing regardless of search path position.

2. Check for an operator accepting exactly the input argument types. If one exists (there can be only one exact match in the set of operators considered), use it. Lack of an exact match creates a security hazard when calling, via qualified name ¹ (not typical), any operator found in a schema that permits untrusted users to create objects. In such situations, cast arguments to force an exact match.

   a. (Optional) If one argument of a binary operator invocation is of the unknown type, then assume it is the same type as the other argument for this check. Invocations involving two unknown inputs, or a prefix operator with an unknown input, will never find a match at this step.

   b. (Optional) If one argument of a binary operator invocation is of the unknown type and the other is of a domain type, next check to see if there is an operator accepting exactly the domain's base type on both sides; if so, use it.

¹ The hazard does not arise with a non-schema-qualified name, because a search path containing schemas that permit untrusted users to create objects is not a secure schema usage pattern.
3. Look for the best match.
   a. Discard candidate operators for which the input types do not match and cannot be converted (using an implicit conversion) to match. \textit{unknown} literals are assumed to be convertible to anything for this purpose. If only one candidate remains, use it; else continue to the next step.
   b. If any input argument is of a domain type, treat it as being of the domain's base type for all subsequent steps. This ensures that domains act like their base types for purposes of ambiguous-operator resolution.
   c. Run through all candidates and keep those with the most exact matches on input types. Keep all candidates if none have exact matches. If only one candidate remains, use it; else continue to the next step.
   d. Run through all candidates and keep those that accept preferred types (of the input data type's type category) at the most positions where type conversion will be required. Keep all candidates if none accept preferred types. If only one candidate remains, use it; else continue to the next step.
   e. If any input arguments are \textit{unknown}, check the type categories accepted at those argument positions by the remaining candidates. At each position, select the \textit{string} category if any candidate accepts that category. (This bias towards string is appropriate since an unknown-type literal looks like a string.) Otherwise, if all the remaining candidates accept the same type category, select that category; otherwise fail because the correct choice cannot be deduced without more clues. Now discard candidates that do not accept the selected type category. Furthermore, if any candidate accepts a preferred type in that category, discard candidates that accept non-preferred types for that argument. Keep all candidates if none survive these tests. If only one candidate remains, use it; else continue to the next step.
   f. If there are both \textit{unknown} and known-type arguments, and all the known-type arguments have the same type, assume that the \textit{unknown} arguments are also of that type, and check which candidates can accept that type at the \textit{unknown}-argument positions. If exactly one candidate passes this test, use it. Otherwise, fail.

Some examples follow.

\textbf{Example 10.1. Square Root Operator Type Resolution}

There is only one square root operator (prefix \texttt{\textbar/}) defined in the standard catalog, and it takes an argument of type \textit{double precision}. The scanner assigns an initial type of \textit{integer} to the argument in this query expression:

\begin{verbatim}
SELECT \texttt{\textbar/} 40 AS "square root of 40";
  square root of 40
-------------------
   6.32455320336759
(1 row)
\end{verbatim}

So the parser does a type conversion on the operand and the query is equivalent to:

\begin{verbatim}
SELECT \texttt{\textbar/} CAST(40 AS double precision) AS "square root of 40";
\end{verbatim}

\textbf{Example 10.2. String Concatenation Operator Type Resolution}

A string-like syntax is used for working with string types and for working with complex extension types. Strings with unspecified type are matched with likely operator candidates.

An example with one unspecified argument:

\begin{verbatim}
SELECT text 'abc' || 'def' AS "text and unknown";
  text and unknown
------------------
   abcdef
\end{verbatim}
In this case the parser looks to see if there is an operator taking text for both arguments. Since there is, it assumes that the second argument should be interpreted as type text.

Here is a concatenation of two values of unspecified types:

```sql
SELECT 'abc' || 'def' AS "unspecified";
```

```
unspecified
-------------
abcdef
```

(1 row)

In this case there is no initial hint for which type to use, since no types are specified in the query. So, the parser looks for all candidate operators and finds that there are candidates accepting both string-category and bit-string-category inputs. Since string category is preferred when available, that category is selected, and then the preferred type for strings, text, is used as the specific type to resolve the unknown-type literals as.

**Example 10.3. Absolute-Value and Negation Operator Type Resolution**

The Postgres Pro operator catalog has several entries for the prefix operator @, all of which implement absolute-value operations for various numeric data types. One of these entries is for type float8, which is the preferred type in the numeric category. Therefore, Postgres Pro will use that entry when faced with an unknown input:

```sql
SELECT @ '-4.5' AS "abs";
```

```
abs
-----
4.5
```

(1 row)

Here the system has implicitly resolved the unknown-type literal as type float8 before applying the chosen operator. We can verify that float8 and not some other type was used:

```sql
SELECT @ '-4.5e500' AS "abs";
```

```
ERROR:  "-4.5e500" is out of range for type double precision
```

On the other hand, the prefix operator ~ (bitwise negation) is defined only for integer data types, not for float8. So, if we try a similar case with ~, we get:

```sql
SELECT ~ '20' AS "negation";
```

```
ERROR:  operator is not unique: ~ "unknown"
HINT:  Could not choose a best candidate operator. You might need to add explicit type casts.
```

This happens because the system cannot decide which of the several possible ~ operators should be preferred. We can help it out with an explicit cast:

```sql
SELECT ~ CAST('20' AS int8) AS "negation";
```

```
negation
--------
-21
```

(1 row)

**Example 10.4. Array Inclusion Operator Type Resolution**

Here is another example of resolving an operator with one known and one unknown input:

```sql
SELECT array[1,2] <@ '{1,2,3}' as "is subset";
```
Type Conversion

The Postgres Pro operator catalog has several entries for the infix operator `<@`, but the only two that could possibly accept an integer array on the left-hand side are array inclusion (`anyarray `<@` anyarray`) and range inclusion (`anyelement `<@` anyrange`). Since none of these polymorphic pseudo-types (see Section 8.21) are considered preferred, the parser cannot resolve the ambiguity on that basis. However, Step 3.f tells it to assume that the unknown-type literal is of the same type as the other input, that is, integer array. Now only one of the two operators can match, so array inclusion is selected. (Had range inclusion been selected, we would have gotten an error, because the string does not have the right format to be a range literal.)

Example 10.5. Custom Operator on a Domain Type

Users sometimes try to declare operators applying just to a domain type. This is possible but is not nearly as useful as it might seem, because the operator resolution rules are designed to select operators applying to the domain’s base type. As an example consider

```
CREATE DOMAIN mytext AS text CHECK(...);
CREATE FUNCTION mytext_eq_text (mytext, text) RETURNS boolean AS ...
CREATE OPERATOR = (procedure=mytext_eq_text, leftarg=mytext, rightarg=text);
CREATE TABLE mytable (val mytext);
SELECT * FROM mytable WHERE val = 'foo';
```

This query will not use the custom operator. The parser will first see if there is a `mytext = mytext` operator (Step 2.a), which there is not; then it will consider the domain’s base type `text`, and see if there is a `text = text` operator (Step 2.b), which there is; so it resolves the unknown-type literal as `text` and uses the `text = text` operator. The only way to get the custom operator to be used is to explicitly cast the literal:

```
SELECT * FROM mytable WHERE val = text 'foo';
```

so that the `mytext = text` operator is found immediately according to the exact-match rule. If the best-match rules are reached, they actively discriminate against operators on domain types. If they did not, such an operator would create too many ambiguous-operator failures, because the casting rules always consider a domain as castable to or from its base type, and so the domain operator would be considered usable in all the same cases as a similarly-named operator on the base type.

10.3. Functions

The specific function that is referenced by a function call is determined using the following procedure.

Function Type Resolution

1. Select the functions to be considered from the `pg_proc` system catalog. If a non-schema-qualified function name was used, the functions considered are those with the matching name and argument count that are visible in the current search path (see Section 5.9.3). If a qualified function name was given, only functions in the specified schema are considered.

   a. (Optional) If the search path finds multiple functions of identical argument types, only the one appearing earliest in the path is considered. Functions of different argument types are considered on an equal footing regardless of search path position.

   b. (Optional) If a function is declared with a `VARIADIC` array parameter, and the call does not use the `VARIADIC` keyword, then the function is treated as if the array parameter were replaced by one or more occurrences of its element type, as needed to match the call. After such expansion the function might have effective argument types identical to some non-variadic function. In that case the function appearing earlier in the search path is used, or if the two functions are in the same schema, the non-variadic one is preferred.
This creates a security hazard when calling, via qualified name, a variadic function found in a schema that permits untrusted users to create objects. A malicious user can take control and execute arbitrary SQL functions as though you executed them. Substitute a call bearing the `VARIADIC` keyword, which bypasses this hazard. Calls populating `VARIADIC "any"` parameters often have no equivalent formulation containing the `VARIADIC` keyword. To issue those calls safely, the function's schema must permit only trusted users to create objects.

c. (Optional) Functions that have default values for parameters are considered to match any call that omits zero or more of the deflatable parameter positions. If more than one such function matches a call, the one appearing earliest in the search path is used. If there are two or more such functions in the same schema with identical parameter types in the non-defaulted positions (which is possible if they have different sets of deflatable parameters), the system will not be able to determine which to prefer, and so an “ambiguous function call” error will result if no better match to the call can be found.

This creates an availability hazard when calling, via qualified name, any function found in a schema that permits untrusted users to create objects. A malicious user can create a function with the name of an existing function, replicating that function's parameters and appending novel parameters having default values. This precludes new calls to the original function. To forestall this hazard, place functions in schemas that permit only trusted users to create objects.

2. Check for a function accepting exactly the input argument types. If one exists (there can be only one exact match in the set of functions considered), use it. Lack of an exact match creates a security hazard when calling, via qualified name, a function found in a schema that permits untrusted users to create objects. In such situations, cast arguments to force an exact match. (Cases involving unknown will never find a match at this step.)

3. If no exact match is found, see if the function call appears to be a special type conversion request. This happens if the function call has just one argument and the function name is the same as the (internal) name of some data type. Furthermore, the function argument must be either an unknown-type literal, or a type that is binary-coercible to the named data type, or a type that could be converted to the named data type by applying that type's I/O functions (that is, the conversion is either to or from one of the standard string types). When these conditions are met, the function call is treated as a form of CAST specification.

4. Look for the best match.
   a. Discard candidate functions for which the input types do not match and cannot be converted (using an implicit conversion) to match. unknown literals are assumed to be convertible to anything for this purpose. If only one candidate remains, use it; else continue to the next step.
   b. If any input argument is of a domain type, treat it as being of the domain's base type for all subsequent steps. This ensures that domains act like their base types for purposes of ambiguous-function resolution.
   c. Run through all candidates and keep those with the most exact matches on input types. Keep all candidates if none have exact matches. If only one candidate remains, use it; else continue to the next step.
   d. Run through all candidates and keep those that accept preferred types (of the input data type's type category) at the most positions where type conversion will be required. Keep all candidates if none accept preferred types. If only one candidate remains, use it; else continue to the next step.
   e. If any input arguments are unknown, check the type categories accepted at those argument positions by the remaining candidates. At each position, select the string category if any candidate accepts that category. (This bias towards string is appropriate since an unknown-type literal looks like a string.) Otherwise, if all the remaining candidates accept the same type

\[\text{2 The hazard does not arise with a non-schema-qualified name, because a search path containing schemas that permit untrusted users to create objects is not a secure schema usage pattern.}\]

\[\text{3 The reason for this step is to support function-style cast specifications in cases where there is not an actual cast function. If there is a cast function, it is conventionally named after its output type, and so there is no need to have a special case. See CREATE CAST for additional commentary.}\]
category, select that category; otherwise fail because the correct choice cannot be deduced without more clues. Now discard candidates that do not accept the selected type category. Furthermore, if any candidate accepts a preferred type in that category, discard candidates that accept non-preferred types for that argument. Keep all candidates if none survive these tests. If only one candidate remains, use it; else continue to the next step.

f. If there are both unknown and known-type arguments, and all the known-type arguments have the same type, assume that the unknown arguments are also of that type, and check which candidates can accept that type at the unknown-argument positions. If exactly one candidate passes this test, use it. Otherwise, fail.

Note that the “best match” rules are identical for operator and function type resolution. Some examples follow.

Example 10.6. Rounding Function Argument Type Resolution

There is only one round function that takes two arguments; it takes a first argument of type numeric and a second argument of type integer. So the following query automatically converts the first argument of type integer to numeric:

```
SELECT round(4, 4);
```

```
round
--------
 4.0000
(1 row)
```

That query is actually transformed by the parser to:

```
SELECT round(CAST (4 AS numeric), 4);
```

Since numeric constants with decimal points are initially assigned the type numeric, the following query will require no type conversion and therefore might be slightly more efficient:

```
SELECT round(4.0, 4);
```

Example 10.7. Variadic Function Resolution

```
CREATE FUNCTION public.variadic_example(VARIADIC numeric[]) RETURNS int
   LANGUAGE sql AS 'SELECT 1';
CREATE FUNCTION

This function accepts, but does not require, the VARIADIC keyword. It tolerates both integer and numeric arguments:

```
SELECT public.variadic_example(0),
    public.variadic_example(0.0),
    public.variadic_example(VARIADIC array[0.0]);
```

```
variadic_example | variadic_example | variadic_example
------------------+------------------+------------------
        1 |                1 |                1
```

(1 row)

However, the first and second calls will prefer more-specific functions, if available:

```
CREATE FUNCTION public.variadic_example(numeric) RETURNS int
   LANGUAGE sql AS 'SELECT 2';
CREATE FUNCTION

CREATE FUNCTION public.variadic_example(int) RETURNS int
   LANGUAGE sql AS 'SELECT 3';
CREATE FUNCTION

SELECT public.variadic_example(0),
        357
public.variadic_example(0.0),
public.variadic_example(VARIADIC array[0.0]);

variadic_example | variadic_example | variadic_example
------------------+------------------+------------------
 3 |                2 |                1

(1 row)

Given the default configuration and only the first function existing, the first and second calls are insecure. Any user could intercept them by creating the second or third function. By matching the argument type exactly and using the VARIADIC keyword, the third call is secure.

**Example 10.8. Substring Function Type Resolution**

There are several `substr` functions, one of which takes types `text` and `integer`. If called with a string constant of unspecified type, the system chooses the candidate function that accepts an argument of the preferred category `string` (namely of type `text`).

```
SELECT substr('1234', 3);
```

```
  substr
--------
     34
(1 row)
```

If the string is declared to be of type `varchar`, as might be the case if it comes from a table, then the parser will try to convert it to become `text`:

```
SELECT substr(varchar '1234', 3);
```

```
  substr
--------
     34
(1 row)
```

This is transformed by the parser to effectively become:

```
SELECT substr(CAST (varchar '1234' AS text), 3);
```

```
Note

The parser learns from the `pg_cast` catalog that `text` and `varchar` are binary-compatible, meaning that one can be passed to a function that accepts the other without doing any physical conversion. Therefore, no type conversion call is really inserted in this case.

And, if the function is called with an argument of type `integer`, the parser will try to convert that to `text`:

```
SELECT substr(1234, 3);
```

**ERROR:**  function substr(integer, integer) does not exist

**HINT:**  No function matches the given name and argument types. You might need to add explicit type casts.

**This does not work because** `integer` **does not have an implicit cast to** `text`. **An explicit cast will work, however:**

```
SELECT substr(CAST (1234 AS text), 3);
```

```
  substr
--------
     34
(1 row)
10.4. Value Storage

Values to be inserted into a table are converted to the destination column’s data type according to the following steps.

Value Storage Type Conversion

1. Check for an exact match with the target.
2. Otherwise, try to convert the expression to the target type. This is possible if an assignment cast between the two types is registered in the pg_cast catalog (see CREATE CAST). Alternatively, if the expression is an unknown-type literal, the contents of the literal string will be fed to the input conversion routine for the target type.
3. Check to see if there is a sizing cast for the target type. A sizing cast is a cast from that type to itself. If one is found in the pg_cast catalog, apply it to the expression before storing into the destination column. The implementation function for such a cast always takes an extra parameter of type integer, which receives the destination column’s atttypmod value (typically its declared length, although the interpretation of atttypmod varies for different data types), and it may take a third boolean parameter that says whether the cast is explicit or implicit. The cast function is responsible for applying any length-dependent semantics such as size checking or truncation.

Example 10.9. character Storage Type Conversion

For a target column declared as character(20) the following statement shows that the stored value is sized correctly:

```
CREATE TABLE vv (v character(20));
INSERT INTO vv SELECT 'abc' || 'def';
SELECT v, octet_length(v) FROM vv;
```

<table>
<thead>
<tr>
<th>v</th>
<th>octet_length</th>
</tr>
</thead>
<tbody>
<tr>
<td>abcdef</td>
<td>20</td>
</tr>
</tbody>
</table>

(1 row)

What has really happened here is that the two unknown literals are resolved to text by default, allowing the || operator to be resolved as text concatenation. Then the text result of the operator is converted to bpchar (“blank-padded char”, the internal name of the character data type) to match the target column type. (Since the conversion from text to bpchar is binary-coercible, this conversion does not insert any real function call.) Finally, the sizing function bpchar(bpchar, integer, boolean) is found in the system catalog and applied to the operator’s result and the stored column length. This type-specific function performs the required length check and addition of padding spaces.

10.5. UNION, CASE, and Related Constructs

SQL UNION constructs must match up possibly dissimilar types to become a single result set. The resolution algorithm is applied separately to each output column of a union query. The INTERSECT and EXCEPT constructs resolve dissimilar types in the same way as UNION. Some other constructs, including CASE, ARRAY, VALUES, and the GREATEST and LEAST functions, use the identical algorithm to match up their component expressions and select a result data type.

Type Resolution for UNION, CASE, and Related Constructs

1. If all inputs are of the same type, and it is not unknown, resolve as that type.
2. If any input is of a domain type, treat it as being of the domain’s base type for all subsequent steps.
3. If all inputs are of type unknown, resolve as type text (the preferred type of the string category). Otherwise, unknown inputs are ignored for the purposes of the remaining rules.

4 Somewhat like the treatment of domain inputs for operators and functions, this behavior allows a domain type to be preserved through a UNION or similar construct, so long as the user is careful to ensure that all inputs are implicitly or explicitly of that exact type. Otherwise the domain’s base type will be used.
4. If the non-unknown inputs are not all of the same type category, fail.

5. Select the first non-unknown input type as the candidate type, then consider each other non-unknown input type, left to right. If the candidate type can be implicitly converted to the other type, but not vice-versa, select the other type as the new candidate type. Then continue considering the remaining inputs. If, at any stage of this process, a preferred type is selected, stop considering additional inputs.

6. Convert all inputs to the final candidate type. Fail if there is not an implicit conversion from a given input type to the candidate type.

Some examples follow.

Example 10.10. Type Resolution with Underspecified Types in a Union

```
SELECT text 'a' AS "text" UNION SELECT 'b';
```

```
text
------
a  b
(2 rows)
```

Here, the unknown-type literal 'b' will be resolved to type text.

Example 10.11. Type Resolution in a Simple Union

```
SELECT 1.2 AS "numeric" UNION SELECT 1;
```

```
numeric
--------
   1
1.2
(2 rows)
```

The literal 1.2 is of type numeric, and the integer value 1 can be cast implicitly to numeric, so that type is used.

Example 10.12. Type Resolution in a Transposed Union

```
SELECT 1 AS "real" UNION SELECT CAST('2.2' AS REAL);
```

```
real
------
   1
   2.2
(2 rows)
```

Here, since type real cannot be implicitly cast to integer, but integer can be implicitly cast to real, the union result type is resolved as real.

Example 10.13. Type Resolution in a Nested Union

```
SELECT NULL UNION SELECT NULL UNION SELECT 1;
```

```
ERROR:  UNION types text and integer cannot be matched
```

This failure occurs because Postgres Pro treats multiple UNIONS as a nest of pairwise operations; that is, this input is the same as

```
(SELECT NULL UNION SELECT NULL) UNION SELECT 1;
```

The inner UNION is resolved as emitting type text, according to the rules given above. Then the outer UNION has inputs of types text and integer, leading to the observed error. The problem can be fixed by ensuring that the leftmost UNION has at least one input of the desired result type.

---

5 For historical reasons, CASE treats its ELSE clause (if any) as the “first” input, with the THEN clauses(s) considered after that. In all other cases, “left to right” means the order in which the expressions appear in the query text.
INTERSECT and EXCEPT operations are likewise resolved pairwise. However, the other constructs described in this section consider all of their inputs in one resolution step.

10.6. SELECT Output Columns

The rules given in the preceding sections will result in assignment of non-unknown data types to all expressions in an SQL query, except for unspecified-type literals that appear as simple output columns of a SELECT command. For example, in

SELECT 'Hello World';

there is nothing to identify what type the string literal should be taken as. In this situation Postgres Pro will fall back to resolving the literal’s type as text.

When the SELECT is one arm of a UNION (or INTERSECT or EXCEPT) construct, or when it appears within INSERT ... SELECT, this rule is not applied since rules given in preceding sections take precedence. The type of an unspecified-type literal can be taken from the other UNION arm in the first case, or from the destination column in the second case.

RETURNING lists are treated the same as SELECT output lists for this purpose.

**Note**

Prior to Postgres Pro 10, this rule did not exist, and unspecified-type literals in a SELECT output list were left as type unknown. That had assorted bad consequences, so it's been changed.
Chapter 11. Indexes

Indexes are a common way to enhance database performance. An index allows the database server to find and retrieve specific rows much faster than it could do without an index. But indexes also add overhead to the database system as a whole, so they should be used sensibly.

11.1. Introduction

Suppose we have a table similar to this:

```
CREATE TABLE test1 (  
id integer,  
  content varchar
);
```

and the application issues many queries of the form:

```
SELECT content FROM test1 WHERE id = constant;
```

With no advance preparation, the system would have to scan the entire `test1` table, row by row, to find all matching entries. If there are many rows in `test1` and only a few rows (perhaps zero or one) that would be returned by such a query, this is clearly an inefficient method. But if the system has been instructed to maintain an index on the `id` column, it can use a more efficient method for locating matching rows. For instance, it might only have to walk a few levels deep into a search tree.

A similar approach is used in most non-fiction books: terms and concepts that are frequently looked up by readers are collected in an alphabetic index at the end of the book. The interested reader can scan the index relatively quickly and flip to the appropriate page(s), rather than having to read the entire book to find the material of interest. Just as it is the task of the author to anticipate the items that readers are likely to look up, it is the task of the database programmer to foresee which indexes will be useful.

The following command can be used to create an index on the `id` column, as discussed:

```
CREATE INDEX test1_id_index ON test1 (id);
```

The name `test1_id_index` can be chosen freely, but you should pick something that enables you to remember later what the index was for:

To remove an index, use the `DROP INDEX` command. Indexes can be added to and removed from tables at any time.

Once an index is created, no further intervention is required: the system will update the index when the table is modified, and it will use the index in queries when it thinks doing so would be more efficient than a sequential table scan. But you might have to run the `ANALYZE` command regularly to update statistics to allow the query planner to make educated decisions. See Chapter 14 for information about how to find out whether an index is used and when and why the planner might choose not to use an index.

Indexes can also benefit `UPDATE` and `DELETE` commands with search conditions. Indexes can moreover be used in join searches. Thus, an index defined on a column that is part of a join condition can also significantly speed up queries with joins.

Creating an index on a large table can take a long time. By default, Postgres Pro allows reads (SELECT statements) to occur on the table in parallel with index creation, but writes (INSERT, UPDATE, DELETE) are blocked until the index build is finished. In production environments this is often unacceptable. It is possible to allow writes to occur in parallel with index creation, but there are several caveats to be aware of — for more information see Building Indexes Concurrently.

After an index is created, the system has to keep it synchronized with the table. This adds overhead to data manipulation operations. Therefore indexes that are seldom or never used in queries should be removed.
11.2. Index Types

Postgres Pro provides several index types: B-tree, Hash, GiST, SP-GiST, GIN and BRIN. Each index type uses a different algorithm that is best suited to different types of queries. By default, the `CREATE INDEX` command creates B-tree indexes, which fit the most common situations. The other index types are selected by writing the keyword `USING` followed by the index type name. For example, to create a Hash index:

```
CREATE INDEX name ON table USING HASH (column);
```

11.2.1. B-Tree

B-trees can handle equality and range queries on data that can be sorted into some ordering. In particular, the Postgres Pro query planner will consider using a B-tree index whenever an indexed column is involved in a comparison using one of these operators:

```
<  <=  =  >=  >
```

Constructs equivalent to combinations of these operators, such as `BETWEEN` and `IN`, can also be implemented with a B-tree index search. Also, an `IS NULL` or `IS NOT NULL` condition on an index column can be used with a B-tree index.

The optimizer can also use a B-tree index for queries involving the pattern matching operators `LIKE` and `~` if the pattern is a constant and is anchored to the beginning of the string — for example, `col LIKE 'foo%'` or `col ~ '^foo'`, but not `col LIKE '%bar'`. However, if your database does not use the C locale you will need to create the index with a special operator class to support indexing of pattern-matching queries; see Section 11.10 below. It is also possible to use B-tree indexes for `ILIKE` and `~*`, but only if the pattern starts with non-alphabetic characters, i.e., characters that are not affected by upper/lower case conversion.

B-tree indexes can also be used to retrieve data in sorted order. This is not always faster than a simple scan and sort, but it is often helpful.

11.2.2. Hash

Hash indexes store a 32-bit hash code derived from the value of the indexed column. Hence, such indexes can only handle simple equality comparisons. The query planner will consider using a hash index whenever an indexed column is involved in a comparison using the equal operator:

```
=
```

11.2.3. GiST

GiST indexes are not a single kind of index, but rather an infrastructure within which many different indexing strategies can be implemented. Accordingly, the particular operators with which a GiST index can be used vary depending on the indexing strategy (the `operator class`). As an example, the standard distribution of Postgres Pro includes GiST operator classes for several two-dimensional geometric data types, which support indexed queries using these operators:

```
<<  <=  >=  >>  <=|  >=|  |<<|  |<=|  |>=|  |>>|  <=@  >=@  =~  &&
```

(See Section 9.11 for the meaning of these operators.) The GiST operator classes included in the standard distribution are documented in Table 61.1. Many other GiST operator classes are available in the contrib collection or as separate projects. For more information see Chapter 61.

GiST indexes are also capable of optimizing “nearest-neighbor” searches, such as

```
SELECT * FROM places ORDER BY location <-> point '(101,456)' LIMIT 10;
```

which finds the ten places closest to a given target point. The ability to do this is again dependent on the particular operator class being used. In Table 61.1, operators that can be used in this way are listed in the column “Ordering Operators”.
11.2.4. SP-GiST

SP-GiST indexes, like GiST indexes, offer an infrastructure that supports various kinds of searches. SP-GiST permits implementation of a wide range of different non-balanced disk-based data structures, such as quadtrees, k-d trees, and radix trees (tries). As an example, the standard distribution of Postgres Pro includes SP-GiST operator classes for two-dimensional points, which support indexed queries using these operators:

\[<< \quad >> \quad ~= \quad <\theta \quad <\mid |>>\]

(See Section 9.11 for the meaning of these operators.) The SP-GiST operator classes included in the standard distribution are documented in Table 62.1. For more information see Chapter 62.

Like GiST, SP-GiST supports “nearest-neighbor” searches. For SP-GiST operator classes that support distance ordering, the corresponding operator is listed in the “Ordering Operators” column in Table 62.1.

11.2.5. GIN

GIN indexes are “inverted indexes” which are appropriate for data values that contain multiple component values, such as arrays. An inverted index contains a separate entry for each component value, and can efficiently handle queries that test for the presence of specific component values.

Like GiST and SP-GiST, GIN can support many different user-defined indexing strategies, and the particular operators with which a GIN index can be used vary depending on the indexing strategy. As an example, the standard distribution of Postgres Pro includes a GIN operator class for arrays, which supports indexed queries using these operators:

\[@ \quad @> \quad = \quad &&\]

(See Section 9.19 for the meaning of these operators.) The GIN operator classes included in the standard distribution are documented in Table 63.1. Many other GIN operator classes are available in the contrib collection or as separate projects. For more information see Chapter 63.

11.2.6. BRIN

BRIN indexes (a shorthand for Block Range INdexes) store summaries about the values stored in consecutive physical block ranges of a table. Thus, they are most effective for columns whose values are well-correlated with the physical order of the table rows. Like GiST, SP-GiST and GIN, BRIN can support many different indexing strategies, and the particular operators with which a BRIN index can be used vary depending on the indexing strategy. For data types that have a linear sort order, the indexed data corresponds to the minimum and maximum values of the values in the column for each block range. This supports indexed queries using these operators:

\[\quad <= \quad = \quad >= \quad >\]

The BRIN operator classes included in the standard distribution are documented in Table 64.1. For more information see Chapter 64.

11.3. Multicolumn Indexes

An index can be defined on more than one column of a table. For example, if you have a table of this form:

```sql
CREATE TABLE test2 (  
major int,  
minor int,  
name varchar
);
```

(say, you keep your /dev directory in a database...) and you frequently issue queries like:

```sql
SELECT name FROM test2 WHERE major = constant AND minor = constant;
```

then it might be appropriate to define an index on the columns `major` and `minor` together, e.g.:

```sql
CREATE INDEX test2_mm_idx ON test2 (major, minor);
```
Indexes

Currently, only the B-tree, GiST, GIN, and BRIN index types support multiple-key-column indexes. Whether there can be multiple key columns is independent of whether INCLUDE columns can be added to the index. Indexes can have up to 32 columns, including INCLUDE columns. (This limit can be altered when building Postgres Pro.)

A multicolumn B-tree index can be used with query conditions that involve any subset of the index's columns, but the index is most efficient when there are constraints on the leading (leftmost) columns. The exact rule is that equality constraints on leading columns, plus any inequality constraints on the first column that does not have an equality constraint, will be used to limit the portion of the index that is scanned. Constraints on columns to the right of these columns are checked in the index, so they save visits to the table proper, but they do not reduce the portion of the index that has to be scanned. For example, given an index on \((a, b, c)\) and a query condition \(a = 5 \text{ AND } b \geq 42 \text{ AND } c < 77\), the index would have to be scanned from the first entry with \(a = 5\) and \(b = 42\) up through the last entry with \(a = 5\). Index entries with \(c \geq 77\) would be skipped, but they'd still have to be scanned through. This index could in principle be used for queries that have constraints on \(b\) and/or \(c\) with no constraint on \(a\) — but the entire index would have to be scanned, so in most cases the planner would prefer a sequential table scan over using the index.

A multicolumn GiST index can be used with query conditions that involve any subset of the index's columns. Conditions on additional columns restrict the entries returned by the index, but the condition on the first column is the most important one for determining how much of the index needs to be scanned. A GiST index will be relatively ineffective if its first column has only a few distinct values, even if there are many distinct values in additional columns.

A multicolumn GIN index can be used with query conditions that involve any subset of the index's columns. Unlike B-tree or GiST, index search effectiveness is the same regardless of which index column(s) the query conditions use.

A multicolumn BRIN index can be used with query conditions that involve any subset of the index's columns. Like GIN and unlike B-tree or GiST, index search effectiveness is the same regardless of which index column(s) the query conditions use. The only reason to have multiple BRIN indexes instead of one multicolumn BRIN index on a single table is to have a different \(\text{pages_per_range}\) storage parameter.

Of course, each column must be used with operators appropriate to the index type; clauses that involve other operators will not be considered.

Multicolumn indexes should be used sparingly. In most situations, an index on a single column is sufficient and saves space and time. Indexes with more than three columns are unlikely to be helpful unless the usage of the table is extremely stylized. See also Section 11.5 and Section 11.9 for some discussion of the merits of different index configurations.

11.4. Indexes and ORDER BY

In addition to simply finding the rows to be returned by a query, an index may be able to deliver them in a specific sorted order. This allows a query's \(\text{ORDER BY}\) specification to be honored without a separate sorting step. Of the index types currently supported by Postgres Pro, only B-tree can produce sorted output — the other index types return matching rows in an unspecified, implementation-dependent order.

The planner will consider satisfying an \(\text{ORDER BY}\) specification either by scanning an available index that matches the specification, or by scanning the table in physical order and doing an explicit sort. For a query that requires scanning a large fraction of the table, an explicit sort is likely to be faster than using an index because it requires less disk I/O due to following a sequential access pattern. Indexes are more useful when only a few rows need be fetched. An important special case is \(\text{ORDER BY}\) in combination with \(\text{LIMIT } n:\) an explicit sort will have to process all the data to identify the first \(n\) rows, but if there is an index matching the \(\text{ORDER BY}\), the first \(n\) rows can be retrieved directly, without scanning the remainder at all.

By default, B-tree indexes store their entries in ascending order with nulls last (table TID is treated as a tiebreaker column among otherwise equal entries). This means that a forward scan of an index on column \(x\) produces output satisfying \(\text{ORDER BY } x\) (or more verbosely, \(\text{ORDER BY } x \text{ ASC NULLS LAST}\)). The
You can adjust the ordering of a B-tree index by including the options ASC, DESC, NULLS FIRST, and/or NULLS LAST when creating the index; for example:

```sql
CREATE INDEX test2_info_nulls_low ON test2 (info NULLS FIRST);
CREATE INDEX test3_desc_index ON test3 (id DESC NULLS LAST);
```

An index stored in ascending order with nulls first can satisfy either ORDER BY x ASC NULLS FIRST or ORDER BY x DESC NULLS LAST depending on which direction it is scanned in.

You might wonder why bother providing all four options, when two options together with the possibility of backward scan would cover all the variants of ORDER BY. In single-column indexes the options are indeed redundant, but in multicolunn indexes they can be useful. Consider a two-column index on (x, y): this can satisfy ORDER BY x, y if we scan forward, or ORDER BY x DESC, y DESC if we scan backward. But it might be that the application frequently needs to use ORDER BY x ASC, y DESC. There is no way to get that ordering from a plain index, but it is possible if the index is defined as (x ASC, y DESC) or (x DESC, y ASC).

Obviously, indexes with non-default sort orderings are a fairly specialized feature, but sometimes they can produce tremendous speedups for certain queries. Whether it's worth maintaining such an index depends on how often you use queries that require a special sort ordering.

### 11.5. Combining Multiple Indexes

A single index scan can only use query clauses that use the index's columns with operators of its operator class and are joined with AND. For example, given an index on (a, b) a query condition like WHERE a = 5 AND b = 6 could use the index, but a query like WHERE a = 5 OR b = 6 could not directly use the index.

Fortunately, Postgres Pro has the ability to combine multiple indexes (including multiple uses of the same index) to handle cases that cannot be implemented by single index scans. The system can form AND and OR conditions across several index scans. For example, a query like WHERE x = 42 OR x = 47 OR x = 53 OR x = 99 could be broken down into four separate scans of an index on x, each scan using one of the query clauses. The results of these scans are then ORed together to produce the result. Another example is that if we have separate indexes on x and y, one possible implementation of a query like WHERE x = 5 AND y = 6 is to use each index with the appropriate query clause and then AND together the index results to identify the result rows.

To combine multiple indexes, the system scans each needed index and prepares a bitmap in memory giving the locations of table rows that are reported as matching that index's conditions. The bitmaps are then ANDed and ORed together as needed by the query. Finally, the actual table rows are visited and returned. The table rows are visited in physical order, because that is how the bitmap is laid out; this means that any ordering of the original indexes is lost, and so a separate sort step will be needed if the query has an ORDER BY clause. For this reason, and because each additional index scan adds extra time, the planner will sometimes choose to use a simple index scan even though additional indexes are available that could have been used as well.

In all but the simplest applications, there are various combinations of indexes that might be useful, and the database developer must make trade-offs to decide which indexes to provide. Sometimes multicolunn indexes are best, but sometimes it's better to create separate indexes and rely on the index-combination feature. For example, if your workload includes a mix of queries that sometimes involve only column x, sometimes only column y, and sometimes both columns, you might choose to create two separate indexes on x and y, relying on index combination to process the queries that use both columns. You could also create a multicolunn index on (x, y). This index would typically be more efficient than index combination for queries involving both columns, but as discussed in Section 11.3, it would be almost useless for queries involving only y, so it should not be the only index. A combination of the multicolunn index and a separate index on y would serve reasonably well. For queries involving only x, the multicolunn index could be used, though it would be larger and hence slower than an index on x alone. The last alternative is to create all three indexes, but this is probably only reasonable if the
Indexes

table is searched much more often than it is updated and all three types of query are common. If one of the types of query is much less common than the others, you'd probably settle for creating just the two indexes that best match the common types.

11.6. Unique Indexes

Indexes can also be used to enforce uniqueness of a column's value, or the uniqueness of the combined values of more than one column.

```
CREATE UNIQUE INDEX name ON table (column [, ...]);
```

Currently, only B-tree indexes can be declared unique.

When an index is declared unique, multiple table rows with equal indexed values are not allowed. Null values are not considered equal. A multicolumn unique index will only reject cases where all indexed columns are equal in multiple rows.

Postgres Pro automatically creates a unique index when a unique constraint or primary key is defined for a table. The index covers the columns that make up the primary key or unique constraint (a multicolumn index, if appropriate), and is the mechanism that enforces the constraint.

**Note**

There's no need to manually create indexes on unique columns; doing so would just duplicate the automatically-created index.

11.7. Indexes on Expressions

An index column need not be just a column of the underlying table, but can be a function or scalar expression computed from one or more columns of the table. This feature is useful to obtain fast access to tables based on the results of computations.

For example, a common way to do case-insensitive comparisons is to use the `lower` function:

```
SELECT * FROM test1 WHERE lower(col1) = 'value';
```

This query can use an index if one has been defined on the result of the `lower(col1)` function:

```
CREATE INDEX test1_lower_col1_idx ON test1 (lower(col1));
```

If we were to declare this index `UNIQUE`, it would prevent creation of rows whose `col1` values differ only in case, as well as rows whose `col1` values are actually identical. Thus, indexes on expressions can be used to enforce constraints that are not definable as simple unique constraints.

As another example, if one often does queries like:

```
SELECT * FROM people WHERE (first_name || ' ' || last_name) = 'John Smith';
```

then it might be worth creating an index like this:

```
CREATE INDEX people_names ON people ((first_name || ' ' || last_name));
```

The syntax of the `CREATE INDEX` command normally requires writing parentheses around index expressions, as shown in the second example. The parentheses can be omitted when the expression is just a function call, as in the first example.

Index expressions are relatively expensive to maintain, because the derived expression(s) must be computed for each row upon insertion and whenever it is updated. However, the index expressions are not recomputed during an indexed search, since they are already stored in the index. In both examples above, the system sees the query as just `WHERE indexedcolumn = 'constant'` and so the speed of the search is equivalent to any other simple index query. Thus, indexes on expressions are useful when retrieval speed is more important than insertion and update speed.
Indexes

11.8. Partial Indexes

A partial index is an index built over a subset of a table; the subset is defined by a conditional expression (called the predicate of the partial index). The index contains entries only for those table rows that satisfy the predicate. Partial indexes are a specialized feature, but there are several situations in which they are useful.

One major reason for using a partial index is to avoid indexing common values. Since a query searching for a common value (one that accounts for more than a few percent of all the table rows) will not use the index anyway, there is no point in keeping those rows in the index at all. This reduces the size of the index, which will speed up those queries that do use the index. It will also speed up many table update operations because the index does not need to be updated in all cases. Example 11.1 shows a possible application of this idea.

Example 11.1. Setting up a Partial Index to Exclude Common Values

Suppose you are storing web server access logs in a database. Most accesses originate from the IP address range of your organization but some are from elsewhere (say, employees on dial-up connections). If your searches by IP are primarily for outside accesses, you probably do not need to index the IP range that corresponds to your organization's subnet.

Assume a table like this:

```
CREATE TABLE access_log (
    url varchar,
    client_ip inet,
    ...
);
```

To create a partial index that suits our example, use a command such as this:

```
CREATE INDEX access_log_client_ip_ix ON access_log (client_ip)
WHERE NOT (client_ip > inet '192.168.100.0' AND client_ip < inet '192.168.100.255');
```

A typical query that can use this index would be:

```
SELECT *
FROM access_log
WHERE url = '/index.html' AND client_ip = inet '212.78.10.32';
```

Here the query's IP address is covered by the partial index. The following query cannot use the partial index, as it uses an IP address that is excluded from the index:

```
SELECT *
FROM access_log
WHERE url = '/index.html' AND client_ip = inet '192.168.100.23';
```

Observe that this kind of partial index requires that the common values be predetermined, so such partial indexes are best used for data distributions that do not change. Such indexes can be recreated occasionally to adjust for new data distributions, but this adds maintenance effort.

Another possible use for a partial index is to exclude values from the index that the typical query workload is not interested in; this is shown in Example 11.2. This results in the same advantages as listed above, but it prevents the “uninteresting” values from being accessed via that index, even if an index scan might be profitable in that case. Obviously, setting up partial indexes for this kind of scenario will require a lot of care and experimentation.

Example 11.2. Setting up a Partial Index to Exclude Uninteresting Values

If you have a table that contains both billed and unbilled orders, where the unbilled orders take up a small fraction of the total table and yet those are the most-accessed rows, you can improve performance by creating an index on just the unbilled rows. The command to create the index would look like this:
Indexes

CREATE INDEX orders_unbilled_index ON orders (order_nr)
    WHERE billed is not true;

A possible query to use this index would be:

SELECT * FROM orders WHERE billed is not true AND order_nr < 10000;

However, the index can also be used in queries that do not involve order_nr at all, e.g.:

SELECT * FROM orders WHERE billed is not true AND amount > 5000.00;

This is not as efficient as a partial index on the amount column would be, since the system has to scan the entire index. Yet, if there are relatively few unbilled orders, using this partial index just to find the unbilled orders could be a win.

Note that this query cannot use this index:

SELECT * FROM orders WHERE order_nr = 3501;

The order 3501 might be among the billed or unbilled orders.

Example 11.2 also illustrates that the indexed column and the column used in the predicate do not need to match. Postgres Pro supports partial indexes with arbitrary predicates, so long as only columns of the table being indexed are involved. However, keep in mind that the predicate must match the conditions used in the queries that are supposed to benefit from the index. To be precise, a partial index can be used in a query only if the system can recognize that the WHERE condition of the query mathematically implies the predicate of the index. Postgres Pro does not have a sophisticated theorem prover that can recognize mathematically equivalent expressions that are written in different forms. (Not only is such a general theorem prover extremely difficult to create, it would probably be too slow to be of any real use.) The system can recognize simple inequality implications, for example “x < 1” implies “x < 2”; otherwise the predicate condition must exactly match part of the query's WHERE condition or the index will not be recognized as usable. Matching takes place at query planning time, not at run time. As a result, parameterized query clauses do not work with a partial index. For example a prepared query with a parameter might specify “x < ?” which will never imply “x < 2” for all possible values of the parameter.

A third possible use for partial indexes does not require the index to be used in queries at all. The idea here is to create a unique index over a subset of a table, as in Example 11.3. This enforces uniqueness among the rows that satisfy the index predicate, without constraining those that do not.

Example 11.3. Setting up a Partial Unique Index

Suppose that we have a table describing test outcomes. We wish to ensure that there is only one “successful” entry for a given subject and target combination, but there might be any number of “unsuccessful” entries. Here is one way to do it:

CREATE TABLE tests (  
    subject text,  
    target text,  
    success boolean,  
    ...
);

CREATE UNIQUE INDEX tests_success_constraint ON tests (subject, target)  
    WHERE success;

This is a particularly efficient approach when there are few successful tests and many unsuccessful ones. It is also possible to allow only one null in a column by creating a unique partial index with an IS NULL restriction.

Finally, a partial index can also be used to override the system's query plan choices. Also, data sets with peculiar distributions might cause the system to use an index when it really should not. In that case the index can be set up so that it is not available for the offending query. Normally, Postgres Pro makes reasonable choices about index usage (e.g., it avoids them when retrieving common values, so the earlier
Indexes

example really only saves index size, it is not required to avoid index usage), and grossly incorrect plan
choices are cause for a bug report.

Keep in mind that setting up a partial index indicates that you know at least as much as the query
planner knows, in particular you know when an index might be profitable. Forming this knowledge
requires experience and understanding of how indexes in Postgres Pro work. In most cases, the
advantage of a partial index over a regular index will be minimal. There are cases where they are quite
counterproductive, as in Example 11.4.

Example 11.4. Do Not Use Partial Indexes as a Substitute for Partitioning

You might be tempted to create a large set of non-overlapping partial indexes, for example

```sql
CREATE INDEX mytable_cat_1 ON mytable (data) WHERE category = 1;
CREATE INDEX mytable_cat_2 ON mytable (data) WHERE category = 2;
CREATE INDEX mytable_cat_3 ON mytable (data) WHERE category = 3;
...,
CREATE INDEX mytable_cat_N ON mytable (data) WHERE category = N;
```

This is a bad idea! Almost certainly, you'll be better off with a single non-partial index, declared like

```sql
CREATE INDEX mytable_cat_data ON mytable (category, data);
```

(Put the category column first, for the reasons described in Section 11.3.) While a search in this larger
index might have to descend through a couple more tree levels than a search in a smaller index, that's
almost certainly going to be cheaper than the planner effort needed to select the appropriate one of the
partial indexes. The core of the problem is that the system does not understand the relationship among
the partial indexes, and will laboriously test each one to see if it’s applicable to the current query.

If your table is large enough that a single index really is a bad idea, you should look into using partitioning
instead (see Section 5.11). With that mechanism, the system does understand that the tables and indexes
are non-overlapping, so far better performance is possible.

More information about partial indexes can be found in ston89b,olson93, and seshadri95.

11.9. Index-Only Scans and Covering Indexes

All indexes in Postgres Pro are secondary indexes, meaning that each index is stored separately from
the table's main data area (which is called the table's heap in Postgres Pro terminology). This means
that in an ordinary index scan, each row retrieval requires fetching data from both the index and the
heap. Furthermore, while the index entries that match a given indexable WHERE condition are usually
close together in the index, the table rows they reference might be anywhere in the heap. The heap-
access portion of an index scan thus involves a lot of random access into the heap, which can be slow,
particularly on traditional rotating media. (As described in Section 11.5, bitmap scans try to alleviate
this cost by doing the heap accesses in sorted order, but that only goes so far.)

To solve this performance problem, Postgres Pro supports index-only scans, which can answer queries
from an index alone without any heap access. The basic idea is to return values directly out of each
index entry instead of consulting the associated heap entry. There are two fundamental restrictions on
when this method can be used:

1. The index type must support index-only scans. B-tree indexes always do. GiST and SP-GiST indexes
   support index-only scans for some operator classes but not others. Other index types have no support.
   The underlying requirement is that the index must physically store, or else be able to reconstruct,
   the original data value for each index entry. As a counterexample, GIN indexes cannot support index-
   only scans because each index entry typically holds only part of the original data value.

2. The query must reference only columns stored in the index. For example, given an index on columns
   x and y of a table that also has a column z, these queries could use index-only scans:

   ```sql
   SELECT x, y FROM tab WHERE x = 'key';
   SELECT x FROM tab WHERE x = 'key' AND y < 42;
   ```

   but these queries could not:
Indexes

SELECT x, z FROM tab WHERE x = 'key';
SELECT x FROM tab WHERE x = 'key' AND z < 42;

(Expression indexes and partial indexes complicate this rule, as discussed below.)

If these two fundamental requirements are met, then all the data values required by the query are available from the index, so an index-only scan is physically possible. But there is an additional requirement for any table scan in Postgres Pro: it must verify that each retrieved row be “visible” to the query’s MVCC snapshot, as discussed in Chapter 13. Visibility information is not stored in index entries, only in heap entries; so at first glance it would seem that every row retrieval would require a heap access anyway. And this is indeed the case, if the table row has been modified recently. However, for seldom-changing data there is a way around this problem. Postgres Pro tracks, for each page in a table’s heap, whether all rows stored in that page are old enough to be visible to all current and future transactions. This information is stored in a bit in the table’s visibility map. An index-only scan, after finding a candidate index entry, checks the visibility map bit for the corresponding heap page. If it’s set, the row is known visible and so the data can be returned with no further work. If it’s not set, the heap entry must be visited to find out whether it’s visible, so no performance advantage is gained over a standard index scan. Even in the successful case, this approach trades visibility map accesses for heap accesses; but since the visibility map is four orders of magnitude smaller than the heap it describes, far less physical I/O is needed to access it. In most situations the visibility map remains cached in memory all the time.

In short, while an index-only scan is possible given the two fundamental requirements, it will be a win only if a significant fraction of the table’s heap pages have their all-visible map bits set. But tables in which a large fraction of the rows are unchanging are common enough to make this type of scan very useful in practice.

To make effective use of the index-only scan feature, you might choose to create a covering index, which is an index specifically designed to include the columns needed by a particular type of query that you run frequently. Since queries typically need to retrieve more columns than just the ones they search on, Postgres Pro allows you to create an index in which some columns are just “payload” and are not part of the search key. This is done by adding an INCLUDE clause listing the extra columns. For example, if you commonly run queries like

```
SELECT y FROM tab WHERE x = 'key';
```

the traditional approach to speeding up such queries would be to create an index on x only. However, an index defined as

```
CREATE INDEX tab_x_y ON tab(x) INCLUDE (y);
```

could handle these queries as index-only scans, because y can be obtained from the index without visiting the heap.

Because column y is not part of the index’s search key, it does not have to be of a data type that the index can handle; it’s merely stored in the index and is not interpreted by the index machinery. Also, if the index is a unique index, that is

```
CREATE UNIQUE INDEX tab_x_y ON tab(x) INCLUDE (y);
```

the uniqueness condition applies to just column x, not to the combination of x and y. (An INCLUDE clause can also be written in UNIQUE and PRIMARY KEY constraints, providing alternative syntax for setting up an index like this.)

It’s wise to be conservative about adding non-key payload columns to an index, especially wide columns. If an index tuple exceeds the maximum size allowed for the index type, data insertion will fail. In any case, non-key columns duplicate data from the index’s table and bloat the size of the index, thus potentially slowing searches. And remember that there is little point in including payload columns in an index unless the table changes slowly enough that an index-only scan is likely to not need to access the heap. If the heap tuple must be visited anyway, it costs nothing more to get the column’s value from there. Other restrictions are that expressions are not currently supported as included columns, and that only B-tree, GiST and SP-GiST indexes currently support included columns.
Indexes

Before Postgres Pro had the INCLUDE feature, people sometimes made covering indexes by writing the payload columns as ordinary index columns, that is writing

```sql
CREATE INDEX tab_x_y ON tab(x, y);
```
even though they had no intention of ever using y as part of a WHERE clause. This works fine as long as the extra columns are trailing columns; making them be leading columns is unwise for the reasons explained in Section 11.3. However, this method doesn't support the case where you want the index to enforce uniqueness on the key column(s).

Suffix truncation always removes non-key columns from upper B-Tree levels. As payload columns, they are never used to guide index scans. The truncation process also removes one or more trailing key column(s) when the remaining prefix of key column(s) happens to be sufficient to describe tuples on the lowest B-Tree level. In practice, covering indexes without an INCLUDE clause often avoid storing columns that are effectively payload in the upper levels. However, explicitly defining payload columns as non-key columns reliably keeps the tuples in upper levels small.

In principle, index-only scans can be used with expression indexes. For example, given an index on f(x) where x is a table column, it should be possible to execute

```sql
SELECT f(x) FROM tab WHERE f(x) < 1;
```
as an index-only scan; and this is very attractive if f() is an expensive-to-compute function. However, Postgres Pro's planner is currently not very smart about such cases. It considers a query to be potentially executable by index-only scan only when all columns needed by the query are available from the index. In this example, x is not needed except in the context f(x), but the planner does not notice that and concludes that an index-only scan is not possible. If an index-only scan seems sufficiently worthwhile, this can be worked around by adding x as an included column, for example

```sql
CREATE INDEX tab_f_x ON tab (f(x)) INCLUDE (x);
```

An additional caveat, if the goal is to avoid recalculating f(x), is that the planner won't necessarily match uses of f(x) that aren't in indexable WHERE clauses to the index column. It will usually get this right in simple queries such as shown above, but not in queries that involve joins. These deficiencies may be remedied in future versions of Postgres Pro.

Partial indexes also have interesting interactions with index-only scans. Consider the partial index shown in Example 11.3:

```sql
CREATE UNIQUE INDEX tests_success_constraint ON tests (subject, target)
    WHERE success;
```

In principle, we could do an index-only scan on this index to satisfy a query like

```sql
SELECT target FROM tests WHERE subject = 'some-subject' AND success;
```

But there's a problem: the WHERE clause refers to success which is not available as a result column of the index. Nonetheless, an index-only scan is possible because the plan does not need to recheck that part of the WHERE clause at run time: all entries found in the index necessarily have success = true so this need not be explicitly checked in the plan. Postgres Pro versions 9.6 and later will recognize such cases and allow index-only scans to be generated, but older versions will not.

11.10. Operator Classes and Operator Families

An index definition can specify an operator class for each column of an index.

```sql
CREATE INDEX name ON table (column opclass [ ( opclass_options ) ] [ sort options ] [, ...]);
```

The operator class identifies the operators to be used by the index for that column. For example, a B-tree index on the type int4 would use the int4_ops class; this operator class includes comparison functions for values of type int4. In practice the default operator class for the column's data type is usually sufficient. The main reason for having operator classes is that for some data types, there could
Indexes

be more than one meaningful index behavior. For example, we might want to sort a complex-number data type either by absolute value or by real part. We could do this by defining two operator classes for the data type and then selecting the proper class when making an index. The operator class determines the basic sort ordering (which can then be modified by adding sort options \texttt{COLLABTE, ASC/DESC} and/or \texttt{NULLS FIRST/NULLS LAST}).

There are also some built-in operator classes besides the default ones:

- The operator classes \texttt{text_pattern_ops}, \texttt{varchar_pattern_ops}, and \texttt{bpchar_pattern_ops} support B-tree indexes on the types \texttt{text}, \texttt{varchar}, and \texttt{char} respectively. The difference from the default operator classes is that the values are compared strictly character by character rather than according to the locale-specific collation rules. This makes these operator classes suitable for use by queries involving pattern matching expressions (\texttt{LIKE} or POSIX regular expressions) when the database does not use the standard “C” locale. As an example, you might index a \texttt{varchar} column like this:

\begin{verbatim}
CREATE INDEX test_index ON test_table (col varchar_pattern_ops);
\end{verbatim}

Note that you should also create an index with the default operator class if you want queries involving ordinary \texttt{<, <=, >, or >=} comparisons to use an index. Such queries cannot use the \texttt{xxx_pattern_ops} operator classes. (Ordinary equality comparisons can use these operator classes, however.) It is possible to create multiple indexes on the same column with different operator classes. If you do use the C locale, you do not need the \texttt{xxx_pattern_ops} operator classes, because an index with the default operator class is usable for pattern-matching queries in the C locale.

The following query shows all defined operator classes:

\begin{verbatim}
SELECT am.amname AS index_method,
    opc.opcname AS opclass_name,
    opc.opctype::regtype AS indexed_type,
    opc.opcdefault AS is_default
FROM pg_am am, pg_opclass opc
WHERE opc.opcmethod = am.oid
ORDER BY index_method, opclass_name;
\end{verbatim}

An operator class is actually just a subset of a larger structure called an \textit{operator family}. In cases where several data types have similar behaviors, it is frequently useful to define cross-data-type operators and allow these to work with indexes. To do this, the operator classes for each of the types must be grouped into the same operator family. The cross-type operators are members of the family, but are not associated with any single class within the family.

This expanded version of the previous query shows the operator family each operator class belongs to:

\begin{verbatim}
SELECT am.amname AS index_method,
    opc.opcname AS opclass_name,
    opf.opfname AS opfamily_name,
    opc.opctype::regtype AS indexed_type,
    opc.opcdefault AS is_default
FROM pg_am am, pg_opfamily opf, pg_opclass opc
WHERE opc.opcmethod = am.oid AND
    opc.opcfamily = opf.oid
ORDER BY index_method, opfamily_name, opfamily_operator;
\end{verbatim}

This query shows all defined operator families and all the operators included in each family:

\begin{verbatim}
SELECT am.amname AS index_method,
    opf.opfname AS opfamily_name,
    amop.amopopr::regoperator AS opfamily_operator
FROM pg_am am, pg_opfamily opf, pg_amop amop
WHERE opf.opfmethod = am.oid AND
    amop.amopfamily = opf.oid
ORDER BY index_method, opfamily_name, opfamily_operator;
\end{verbatim}
11.11. Indexes and Collations

An index can support only one collation per index column. If multiple collations are of interest, multiple indexes may be needed.

Consider these statements:

```sql
CREATE TABLE test1c (
    id integer,
    content varchar COLLATE "x"
);

CREATE INDEX test1c_content_index ON test1c (content);
```

The index automatically uses the collation of the underlying column. So a query of the form

```sql
SELECT * FROM test1c WHERE content > constant;
```

could use the index, because the comparison will by default use the collation of the column. However, this index cannot accelerate queries that involve some other collation. So if queries of the form, say,

```sql
SELECT * FROM test1c WHERE content > constant COLLATE "y";
```

are also of interest, an additional index could be created that supports the "y" collation, like this:

```sql
CREATE INDEX test1c_content_y_index ON test1c (content COLLATE "y");
```

11.12. Examining Index Usage

Although indexes in Postgres Pro do not need maintenance or tuning, it is still important to check which indexes are actually used by the real-life query workload. Examining index usage for an individual query is done with the `EXPLAIN` command; its application for this purpose is illustrated in Section 14.1. It is also possible to gather overall statistics about index usage in a running server, as described in Section 26.2.

It is difficult to formulate a general procedure for determining which indexes to create. There are a number of typical cases that have been shown in the examples throughout the previous sections. A good deal of experimentation is often necessary. The rest of this section gives some tips for that:

- Always run `ANALYZE` first. This command collects statistics about the distribution of the values in the table. This information is required to estimate the number of rows returned by a query, which is needed by the planner to assign realistic costs to each possible query plan. In absence of any real statistics, some default values are assumed, which are almost certain to be inaccurate. Examining an application's index usage without having run `ANALYZE` is therefore a lost cause. See Section 23.1.3 and Section 23.1.6 for more information.

- Use real data for experimentation. Using test data for setting up indexes will tell you what indexes you need for the test data, but that is all.

It is especially fatal to use very small test data sets. While selecting 1000 out of 100000 rows could be a candidate for an index, selecting 1 out of 100 rows will hardly be, because the 100 rows probably fit within a single disk page, and there is no plan that can beat sequentially fetching 1 disk page.

Also be careful when making up test data, which is often unavoidable when the application is not yet in production. Values that are very similar, completely random, or inserted in sorted order will skew the statistics away from the distribution that real data would have.
Indexes

- When indexes are not used, it can be useful for testing to force their use. There are run-time parameters that can turn off various plan types (see Section 18.7.1). For instance, turning off sequential scans (enable_seqscan) and nested-loop joins (enable_nestloop), which are the most basic plans, will force the system to use a different plan. If the system still chooses a sequential scan or nested-loop join then there is probably a more fundamental reason why the index is not being used; for example, the query condition does not match the index. (What kind of query can use what kind of index is explained in the previous sections.)

- If forcing index usage does use the index, then there are two possibilities: Either the system is right and using the index is indeed not appropriate, or the cost estimates of the query plans are not reflecting reality. So you should time your query with and without indexes. The `EXPLAIN ANALYZE` command can be useful here.

- If it turns out that the cost estimates are wrong, there are, again, two possibilities. The total cost is computed from the per-row costs of each plan node times the selectivity estimate of the plan node. The costs estimated for the plan nodes can be adjusted via run-time parameters (described in Section 18.7.2). An inaccurate selectivity estimate is due to insufficient statistics. It might be possible to improve this by tuning the statistics-gathering parameters (see `ALTER TABLE`).

If you do not succeed in adjusting the costs to be more appropriate, then you might have to resort to forcing index usage explicitly. You might also want to contact the Postgres Pro developers to examine the issue.
Chapter 12. Full Text Search

12.1. Introduction

Full Text Searching (or just text search) provides the capability to identify natural-language documents that satisfy a query, and optionally to sort them by relevance to the query. The most common type of search is to find all documents containing given query terms and return them in order of their similarity to the query. Notions of query and similarity are very flexible and depend on the specific application. The simplest search considers query as a set of words and similarity as the frequency of query words in the document.

Textual search operators have existed in databases for years. Postgres Pro has ~, ~*, LIKE, and ILIKE operators for textual data types, but they lack many essential properties required by modern information systems:

• There is no linguistic support, even for English. Regular expressions are not sufficient because they cannot easily handle derived words, e.g., satisfies and satisfy. You might miss documents that contain satisfies, although you probably would like to find them when searching for satisfy. It is possible to use OR to search for multiple derived forms, but this is tedious and error-prone (some words can have several thousand derivatives).
• They provide no ordering (ranking) of search results, which makes them ineffective when thousands of matching documents are found.
• They tend to be slow because there is no index support, so they must process all documents for every search.

Full text indexing allows documents to be preprocessed and an index saved for later rapid searching. Preprocessing includes:

Parsing documents into tokens. It is useful to identify various classes of tokens, e.g., numbers, words, complex words, email addresses, so that they can be processed differently. In principle token classes depend on the specific application, but for most purposes it is adequate to use a predefined set of classes. Postgres Pro uses a parser to perform this step. A standard parser is provided, and custom parsers can be created for specific needs.

Converting tokens into lexemes. A lexeme is a string, just like a token, but it has been normalized so that different forms of the same word are made alike. For example, normalization almost always includes folding upper-case letters to lower-case, and often involves removal of suffixes (such as s or es in English). This allows searches to find variant forms of the same word, without tediously entering all the possible variants. Also, this step typically eliminates stop words, which are words that are so common that they are useless for searching. (In short, then, tokens are raw fragments of the document text, while lexemes are words that are believed useful for indexing and searching.) Postgres Pro uses dictionaries to perform this step. Various standard dictionaries are provided, and custom ones can be created for specific needs.

Storing preprocessed documents optimized for searching. For example, each document can be represented as a sorted array of normalized lexemes. Along with the lexemes it is often desirable to store positional information to use for proximity ranking, so that a document that contains a more “dense” region of query words is assigned a higher rank than one with scattered query words.

Dictionaries allow fine-grained control over how tokens are normalized. With appropriate dictionaries, you can:

• Define stop words that should not be indexed.
• Map synonyms to a single word using Ispell.
• Map phrases to a single word using a thesaurus.
• Map different variations of a word to a canonical form using an Ispell dictionary.
• Map different variations of a word to a canonical form using Snowball stemmer rules.

A data type tsvector is provided for storing preprocessed documents, along with a type tsquery for representing processed queries (Section 8.11). There are many functions and operators available
for these data types (Section 9.13), the most important of which is the match operator @@, which we introduce in Section 12.1.2. Full text searches can be accelerated using indexes (Section 12.9).

12.1.1. What Is a Document?

A document is the unit of searching in a full text search system; for example, a magazine article or email message. The text search engine must be able to parse documents and store associations of lexemes (key words) with their parent document. Later, these associations are used to search for documents that contain query words.

For searches within Postgres Pro, a document is normally a textual field within a row of a database table, or possibly a combination (concatenation) of such fields, perhaps stored in several tables or obtained dynamically. In other words, a document can be constructed from different parts for indexing and it might not be stored anywhere as a whole. For example:

```sql
SELECT title || ' ' || author || ' ' || abstract || ' ' || body AS document
FROM messages
WHERE mid = 12;

SELECT m.title || ' ' || m.author || ' ' || m.abstract || ' ' || d.body AS document
FROM messages m, docs d
WHERE m.mid = d.did AND m.mid = 12;
```

Note

Actually, in these example queries, coalesce should be used to prevent a single NULL attribute from causing a NULL result for the whole document.

Another possibility is to store the documents as simple text files in the file system. In this case, the database can be used to store the full text index and to execute searches, and some unique identifier can be used to retrieve the document from the file system. However, retrieving files from outside the database requires superuser permissions or special function support, so this is usually less convenient than keeping all the data inside Postgres Pro. Also, keeping everything inside the database allows easy access to document metadata to assist in indexing and display.

For text search purposes, each document must be reduced to the preprocessed `tsvector` format. Searching and ranking are performed entirely on the `tsvector` representation of a document — the original text need only be retrieved when the document has been selected for display to a user. We therefore often speak of the `tsvector` as being the document, but of course it is only a compact representation of the full document.

12.1.2. Basic Text Matching

Full text searching in Postgres Pro is based on the match operator @@, which returns true if a `tsvector` (document) matches a `tsquery` (query). It doesn't matter which data type is written first:

```sql
SELECT 'a fat cat sat on a mat and ate a fat rat':tsvector @@ 'cat & rat':tsquery;
?column?
----------
t

SELECT 'fat & cow':tsquery @@ 'a fat cat sat on a mat and ate a fat rat':tsvector;
?column?
----------
f
```

As the above example suggests, a `tsquery` is not just raw text, any more than a `tsvector` is. A `tsquery` contains search terms, which must be already-normalized lexemes, and may combine multiple terms using AND, OR, NOT, and FOLLOWED BY operators. (For syntax details see Section 8.11.2.) There are functions `to_tsquery`, `plainto_tsquery`, and `phraseto_tsquery` that are helpful in converting user-
written text into a proper tsquery, primarily by normalizing words appearing in the text. Similarly, to_tsvector is used to parse and normalize a document string. So in practice a text search match would look more like this:

```
SELECT to_tsvector('fat cats ate fat rats') @@ to_tsquery('fat & rat');
```

Observe that this match would not succeed if written as

```
SELECT 'fat cats ate fat rats'::tsvector @@ to_tsquery('fat & rat');
```

since here no normalization of the word rats will occur. The elements of a tsvector are lexemes, which are assumed already normalized, so rats does not match rat.

The @@ operator also supports text input, allowing explicit conversion of a text string to tsvector or tsquery to be skipped in simple cases. The variants available are:

```
tsvector @@ tsquery
tsquery @@ tsvector
text @@ tsquery
text @@ text
```

The first two of these we saw already. The form `text @@ tsquery` is equivalent to `to_tsvector(x) @@ y`. The form `text @@ text` is equivalent to `to_tsvector(x) @@ plainto_tsquery(y)`.

Within a tsquery, the & (AND) operator specifies that both its arguments must appear in the document to have a match. Similarly, the | (OR) operator specifies that at least one of its arguments must appear, while the ! (NOT) operator specifies that its argument must not appear in order to have a match. For example, the query `fat & ! rat` matches documents that contain fat but not rat.

Searching for phrases is possible with the help of the <-> (FOLLOWED BY) tsquery operator, which matches only if its arguments have matches that are adjacent and in the given order. For example:

```
SELECT to_tsvector('fatal error') @@ to_tsquery('fatal <-> error');
```

```
SELECT to_tsvector('error is not fatal') @@ to_tsquery('fatal <-> error');
```

There is a more general version of the FOLLOWED BY operator having the form `<N>`, where `N` is an integer standing for the difference between the positions of the matching lexemes. `<1>` is the same as <->, while `<2>` allows exactly one other lexeme to appear between the matches, and so on. The phraseto_tsquery function makes use of this operator to construct a tsquery that can match a multi-word phrase when some of the words are stop words. For example:

```
SELECT phraseto_tsquery('cats ate rats');
```

```
SELECT phraseto_tsquery('the cats ate the rats');
```
A special case that's sometimes useful is that \(<0>\) can be used to require that two patterns match the same word.

Parentheses can be used to control nesting of the tsquery operators. Without parentheses, | binds least tightly, then & then <->, and ! most tightly.

It's worth noticing that the AND/OR/NOT operators mean something subtly different when they are within the arguments of a FOLLOWED BY operator than when they are not, because within FOLLOWED BY the exact position of the match is significant. For example, normally !x matches only documents that do not contain x anywhere. But !x <-> y matches y if it is not immediately after an x; an occurrence of x elsewhere in the document does not prevent a match. Another example is that x & y normally only requires that x and y both appear somewhere in the document, but (x & y) <-> z requires x and y to match at the same place, immediately before a z. Thus this query behaves differently from x <-> z & y <-> z, which will match a document containing two separate sequences x z and y z. (This specific query is useless as written, since x and y could not match at the same place; but with more complex situations such as prefix-match patterns, a query of this form could be useful.)

12.1.3. Configurations

The above are all simple text search examples. As mentioned before, full text search functionality includes the ability to do many more things: skip indexing certain words (stop words), process synonyms, and use sophisticated parsing, e.g., parse based on more than just white space. This functionality is controlled by text search configurations. Postgres Pro comes with predefined configurations for many languages, and you can easily create your own configurations. (psql's \dF command shows all available configurations.)

During installation an appropriate configuration is selected and default_text_search_config is set accordingly in postgresql.conf. If you are using the same text search configuration for the entire cluster you can use the value in postgresql.conf. To use different configurations throughout the cluster but the same configuration within any one database, use ALTER DATABASE ... SET. Otherwise, you can set default_text_search_config in each session.

Each text search function that depends on a configuration has an optional regconfig argument, so that the configuration to use can be specified explicitly. default_text_search_config is used only when this argument is omitted.

To make it easier to build custom text search configurations, a configuration is built up from simpler database objects. Postgres Pro’s text search facility provides four types of configuration-related database objects:

- **Text search parsers** break documents into tokens and classify each token (for example, as words or numbers).
- **Text search dictionaries** convert tokens to normalized form and reject stop words.
- **Text search templates** provide the functions underlying dictionaries. (A dictionary simply specifies a template and a set of parameters for the template.)
- **Text search configurations** select a parser and a set of dictionaries to use to normalize the tokens produced by the parser.

Text search parsers and templates are built from low-level C functions; therefore it requires C programming ability to develop new ones, and superuser privileges to install one into a database. (There are examples of add-on parsers and templates in the contrib/ area of the Postgres Pro distribution.) Since dictionaries and configurations just parameterize and connect together some underlying parsers and templates, no special privilege is needed to create a new dictionary or configuration. Examples of creating custom dictionaries and configurations appear later in this chapter.

12.2. Tables and Indexes

The examples in the previous section illustrated full text matching using simple constant strings. This section shows how to search table data, optionally using indexes.
12.2.1. Searching a Table

It is possible to do a full text search without an index. A simple query to print the title of each row that contains the word friend in its body field is:

```
SELECT title
FROM pgweb
WHERE to_tsvector('english', body) @@ to_tsquery('english', 'friend');
```

This will also find related words such as friends and friendly, since all these are reduced to the same normalized lexeme.

The query above specifies that the english configuration is to be used to parse and normalize the strings. Alternatively we could omit the configuration parameters:

```
SELECT title
FROM pgweb
WHERE to_tsvector(body) @@ to_tsquery('friend');
```

This query will use the configuration set by default_text_search_config.

A more complex example is to select the ten most recent documents that contain create and table in the title or body:

```
SELECT title
FROM pgweb
WHERE to_tsvector(title || ' ' || body) @@ to_tsquery('create & table')
ORDER BY last_mod_date DESC
LIMIT 10;
```

For clarity we omitted the coalesce function calls which would be needed to find rows that contain NULL in one of the two fields.

Although these queries will work without an index, most applications will find this approach too slow, except perhaps for occasional ad-hoc searches. Practical use of text searching usually requires creating an index.

12.2.2. Creating Indexes

We can create a GIN index (Section 12.9) to speed up text searches:

```
CREATE INDEX pgweb_idx ON pgweb USING GIN (to_tsvector('english', body));
```

Notice that the 2-argument version of to_tsvector is used. Only text search functions that specify a configuration name can be used in expression indexes (Section 11.7). This is because the index contents must be unaffected by default_text_search_config. If they were affected, the index contents might be inconsistent because different entries could contain tsvector that were created with different text search configurations, and there would be no way to guess which was which. It would be impossible to dump and restore such an index correctly.

Because the two-argument version of to_tsvector was used in the index above, only a query reference that uses the 2-argument version of to_tsvector with the same configuration name will use that index. That is, WHERE to_tsvector('english', body) @@ 'a & b' can use the index, but WHERE to_tsvector(body) @@ 'a & b' cannot. This ensures that an index will be used only with the same configuration used to create the index entries.

It is possible to set up more complex expression indexes wherein the configuration name is specified by another column, e.g.:

```
CREATE INDEX pgweb_idx ON pgweb USING GIN (to_tsvector(config_name, body));
```

where config_name is a column in the pgweb table. This allows mixed configurations in the same index while recording which configuration was used for each index entry. This would be useful, for example, if
the document collection contained documents in different languages. Again, queries that are meant to use the index must be phrased to match, e.g., WHERE to_tsvector(config_name, body) @@ 'a & b'.

Indexes can even concatenate columns:

CREATE INDEX pgweb_idx ON pgweb USING GIN (to_tsvector('english', title || ' ' || body));

Another approach is to create a separate tsvector column to hold the output of to_tsvector. To keep this column automatically up to date with its source data, use a stored generated column. This example is a concatenation of title and body, using coalesce to ensure that one field will still be indexed when the other is NULL:

ALTER TABLE pgweb
  ADD COLUMN searchable_index_col tsvector
    GENERATED ALWAYS AS (to_tsvector('english', coalesce(title, '') || ' ' || coalesce(body, ''))) STORED;

Then we create a GIN index to speed up the search:

CREATE INDEX textsearch_idx ON pgweb USING GIN (searchable_index_col);

Now we are ready to perform a fast full text search:

SELECT title
FROM pgweb
WHERE searchable_index_col @@ to_tsquery('create & table')
ORDER BY last_mod_date DESC
LIMIT 10;

One advantage of the separate-column approach over an expression index is that it is not necessary to explicitly specify the text search configuration in queries in order to make use of the index. As shown in the example above, the query can depend on default_text_search_config. Another advantage is that searches will be faster, since it will not be necessary to redo the to_tsvector calls to verify index matches. (This is more important when using a GiST index than a GIN index; see Section 12.9.) The expression-index approach is simpler to set up, however, and it requires less disk space since the tsvector representation is not stored explicitly.

12.3. Controlling Text Search

To implement full text searching there must be a function to create a tsvector from a document and a tsquery from a user query. Also, we need to return results in a useful order, so we need a function that compares documents with respect to their relevance to the query. It's also important to be able to display the results nicely. Postgres Pro provides support for all of these functions.

12.3.1. Parsing Documents

Postgres Pro provides the function to_tsvector for converting a document to the tsvector data type.

to_tsvector([ config regconfig, ] document text) returns tsvector

to_tsvector parses a textual document into tokens, reduces the tokens to lexemes, and returns a tsvector which lists the lexemes together with their positions in the document. The document is processed according to the specified or default text search configuration. Here is a simple example:

SELECT to_tsvector('english', 'a fat cat sat on a mat - it ate a fat rats');
to_tsvector
-----------------------------
'ate':9 'cat':3 'fat':2,11 'mat':7 'rat':12 'sat':4

In the example above we see that the resulting tsvector does not contain the words a, on, or it, the word rats became rat, and the punctuation sign - was ignored.
The `to_tsvector` function internally calls a parser which breaks the document text into tokens and assigns a type to each token. For each token, a list of dictionaries (Section 12.6) is consulted, where the list can vary depending on the token type. The first dictionary that recognizes the token emits one or more normalized lexemes to represent the token. For example, `rats` became `rat` because one of the dictionaries recognized that the word `rats` is a plural form of `rat`. Some words are recognized as stop words (Section 12.6.1), which causes them to be ignored since they occur too frequently to be useful in searching. In our example these are `a`, `on`, and `it`. If no dictionary in the list recognizes the token then it is also ignored. In this example that happened to the punctuation sign – because there are in fact no dictionaries assigned for its token type (Space symbols), meaning space tokens will never be indexed. The choices of parser, dictionaries and which types of tokens to index are determined by the selected text search configuration (Section 12.7). It is possible to have many different configurations in the same database, and predefined configurations are available for various languages. In our example we used the default configuration `english` for the English language.

The function `setweight` can be used to label the entries of a `tsvector` with a given `weight`, where a weight is one of the letters `A`, `B`, `C`, or `D`. This is typically used to mark entries coming from different parts of a document, such as title versus body. Later, this information can be used for ranking of search results.

Because `to_tsvector(NULL)` will return `NULL`, it is recommended to use `coalesce` whenever a field might be null. Here is the recommended method for creating a `tsvector` from a structured document:

```sql
UPDATE tt SET ti =
  setweight(to_tsvector(coalesce(title,''')), 'A') ||
  setweight(to_tsvector(coalesce(keyword,''')), 'B') ||
  setweight(to_tsvector(coalesce(abstract,''')), 'C') ||
  setweight(to_tsvector(coalesce(body,''')), 'D');
```

Here we have used `setweight` to label the source of each lexeme in the finished `tsvector`, and then merged the labeled `tsvector` values using the `tsvector` concatenation operator `||`. (Section 12.4.1 gives details about these operations.)

### 12.3.2. Parsing Queries

Postgres Pro provides the functions `to_tsquery`, `plainto_tsquery`, `phraseto_tsquery` and `websearch_to_tsquery` for converting a query to the `tsquery` data type. `to_tsquery` offers access to more features than either `plainto_tsquery` or `phraseto_tsquery`, but it is less forgiving about its input. `websearch_to_tsquery` is a simplified version of `to_tsquery` with an alternative syntax, similar to the one used by web search engines.

```sql

to_query([ config regconfig, ] querytext text) returns tsquery
```

`to_tsquery` creates a `tsquery` value from `querytext`, which must consist of single tokens separated by the `tsquery` operators `&` (AND), `|` (OR), `!` (NOT), and `<->` (FOLLOWED BY), possibly grouped using parentheses. In other words, the input to `to_tsquery` must already follow the general rules for `tsquery` input, as described in Section 8.11.2. The difference is that while basic `tsquery` input takes the tokens at face value, `to_tsquery` normalizes each token into a lexeme using the specified or default configuration, and discards any tokens that are stop words according to the configuration. For example:

```sql
SELECT to_tsquery('english', 'The & Fat & Rats');

  to_tsquery
    'fat' & 'rat'
```

As in basic `tsquery` input, weight(s) can be attached to each lexeme to restrict it to match only `tsvector` lexemes of those weight(s). For example:

```sql
SELECT to_tsquery('english', 'Fat | Rats:AB');

  to_tsquery
    'fat' | 'rat':AB
```
Also, * can be attached to a lexeme to specify prefix matching:

```
SELECT to_tsquery('supern:*A & star:A*B');
```

```
to_tsquery('supern':*A & 'star':*AB
```

Such a lexeme will match any word in a tsvector that begins with the given string.

to_tsquery can also accept single-quoted phrases. This is primarily useful when the configuration includes a thesaurus dictionary that may trigger on such phrases. In the example below, a thesaurus contains the rule supernovae stars : sn:

```
SELECT to_tsquery('''supernovae stars'' & !crab');
```

```
to_tsquery('sn' & !'crab'
```

Without quotes, to_tsquery will generate a syntax error for tokens that are not separated by an AND, OR, or FOLLOWED BY operator.

plainto_tsquery([ config regconfig, ] querytext text) returns tsquery

plainto_tsquery transforms the unformatted text querytext to a tsquery value. The text is parsed and normalized much as for to_tsvector, then the & (AND) tsquery operator is inserted between surviving words.

Example:

```
SELECT plainto_tsquery('english', 'The Fat Rats');
```

```
plainto_tsquery('fat' & 'rat'
```

Note that plainto_tsquery will not recognize tsquery operators, weight labels, or prefix-match labels in its input:

```
SELECT plainto_tsquery('english', 'The Fat & Rats:C');
```

```
plainto_tsquery('fat' & 'rat' & 'c'
```

Here, all the input punctuation was discarded.

phraseto_tsquery([ config regconfig, ] querytext text) returns tsquery

phraseto_tsquery behaves much like plainto_tsquery, except that it inserts the <-> (FOLLOWED BY) operator between surviving words instead of the & (AND) operator. Also, stop words are not simply discarded, but are accounted for by inserting <N> operators rather than <-> operators. This function is useful when searching for exact lexeme sequences, since the FOLLOWED BY operators check lexeme order not just the presence of all the lexemes.

Example:

```
SELECT phraseto_tsquery('english', 'The Fat Rats');
```

```
phraseto_tsquery('fat' <-> 'rat'
```

Like plainto_tsquery, the phraseto_tsquery function will not recognize tsquery operators, weight labels, or prefix-match labels in its input:

```
SELECT phraseto_tsquery('english', 'The Fat & Rats:C');
```

```
phraseto_tsquery('fat' & 'rat' & 'c'
```
websearch_to_tsquery creates a tsquery value from querytext using an alternative syntax in which simple unformatted text is a valid query. Unlike plainto_tsquery and phraseto_tsquery, it also recognizes certain operators. Moreover, this function will never raise syntax errors, which makes it possible to use raw user-supplied input for search. The following syntax is supported:

- **unquoted text**: text not inside quote marks will be converted to terms separated by & operators, as if processed by plainto_tsquery.
- **"quoted text"**: text inside quote marks will be converted to terms separated by <-> operators, as if processed by phraseto_tsquery.
- **OR**: the word “or” will be converted to the | operator.
- **!**: a dash will be converted to the ! operator.

Other punctuation is ignored. So like plainto_tsquery and phraseto_tsquery, the websearch_to_tsquery function will not recognize tsquery operators, weight labels, or prefix-match labels in its input.

**Examples:**

```sql
SELECT websearch_to_tsquery('english', 'The fat rats');
websearch_to_tsquery
----------------------------------
'fat' & 'rat'
(1 row)

SELECT websearch_to_tsquery('english', '"supernovae stars" -crab');
websearch_to_tsquery
-----------------------------------
'supernova' <-> 'star' & !'crab'
(1 row)

SELECT websearch_to_tsquery('english', '"sad cat" or "fat rat"');
websearch_to_tsquery
-------------------------------------
'sad' <-> 'cat' | 'fat' <-> 'rat'
(1 row)

SELECT websearch_to_tsquery('english', 'signal -"segmentation fault"');
websearch_to_tsquery
--------------------------------------
'signal' & !{ 'segment' <-> 'fault' }
(1 row)

SELECT websearch_to_tsquery('english', """") ( dummy \ \ query <->');
websearch_to_tsquery
----------------------
'dummi' & 'queri'
(1 row)
```

### 12.3.3. Ranking Search Results

Ranking attempts to measure how relevant documents are to a particular query, so that when there are many matches the most relevant ones can be shown first. Postgres Pro provides two predefined ranking functions, which take into account lexical, proximity, and structural information; that is, they consider how often the query terms appear in the document, how close together the terms are in the document, and how important is the part of the document where they occur. However, the concept of relevancy is vague and very application-specific. Different applications might require additional information for ranking, e.g., document modification time. The built-in ranking functions are only examples. You can
write your own ranking functions and/or combine their results with additional factors to fit your specific needs.

The two ranking functions currently available are:

\[
\text{ts_rank}([\text{weights \ float4[]}], \text{vector tsvector}, \text{query tsquery}, [\text{normalization integer}]) \text{ returns float4}
\]

Ranks vectors based on the frequency of their matching lexemes.

\[
\text{ts_rank_cd}([\text{weights \ float4[]}], \text{vector tsvector}, \text{query tsquery}, [\text{normalization integer}]) \text{ returns float4}
\]

This function computes the cover density ranking for the given document vector and query, as described in Clarke, Cormack, and Tudhope's "Relevance Ranking for One to Three Term Queries" in the journal "Information Processing and Management", 1999. Cover density is similar to \text{ts_rank} ranking except that the proximity of matching lexemes to each other is taken into consideration.

This function requires lexeme positional information to perform its calculation. Therefore, it ignores any "stripped" lexemes in the \text{tsvector}. If there are no unstripped lexemes in the input, the result will be zero. (See Section 12.4.1 for more information about the \text{strip} function and positional information in \text{tsvector}s.)

For both these functions, the optional \text{weights} argument offers the ability to weigh word instances more or less heavily depending on how they are labeled. The weight arrays specify how heavily to weigh each category of word, in the order:

(D-weight, C-weight, B-weight, A-weight)

If no \text{weights} are provided, then these defaults are used:

(0.1, 0.2, 0.4, 1.0)

Typically weights are used to mark words from special areas of the document, like the title or an initial abstract, so they can be treated with more or less importance than words in the document body.

Since a longer document has a greater chance of containing a query term it is reasonable to take into account document size, e.g., a hundred-word document with five instances of a search word is probably more relevant than a thousand-word document with five instances. Both ranking functions take an integer \text{normalization} option that specifies whether and how a document's length should impact its rank. The integer option controls several behaviors, so it is a bit mask: you can specify one or more behaviors using | (for example, \texttt{2|4}).

- 0 (the default) ignores the document length
- 1 divides the rank by 1 + the logarithm of the document length
- 2 divides the rank by the document length
- 4 divides the rank by the mean harmonic distance between extents (this is implemented only by \text{ts_rank_cd})
- 8 divides the rank by the number of unique words in document
- 16 divides the rank by 1 + the logarithm of the number of unique words in document
- 32 divides the rank by itself + 1

If more than one flag bit is specified, the transformations are applied in the order listed.

It is important to note that the ranking functions do not use any global information, so it is impossible to produce a fair normalization to 1% or 100% as sometimes desired. Normalization option 32 (\text{rank}/(\text{rank} +1)) can be applied to scale all ranks into the range zero to one, but of course this is just a cosmetic change; it will not affect the ordering of the search results.

Here is an example that selects only the ten highest-ranked matches:

\[
\begin{align*}
\text{SELECT title, ts_rank_cd(textsearch, query) AS rank} \\
\text{FROM apod, to_tsquery('neutrino|(dark & matter)') query} \\
\text{WHERE query @@ textsearch} \\
\text{ORDER BY rank DESC}
\end{align*}
\]
**12.3.4. Highlighting Results**

To present search results it is ideal to show a part of each document and how it is related to the query. Usually, search engines show fragments of the document with marked search terms. Postgres Pro provides a function `ts_headline` that implements this functionality.

```sql
ts_headline([ config regconfig, ] document text, query tsquery [, options text ]) returns text
```

`ts_headline` accepts a document along with a query, and returns an excerpt from the document in which terms from the query are highlighted. The configuration to be used to parse the document can be specified by `config`; if `config` is omitted, the `default_text_search_config` configuration is used.

If an `options` string is specified it must consist of a comma-separated list of one or more `option=value` pairs. The available options are:

- **MaxWords, MinWords** (integers): these numbers determine the longest and shortest headlines to output. The default values are 35 and 15.
- **ShortWord** (integer): words of this length or less will be dropped at the start and end of a headline, unless they are query terms. The default value of three eliminates common English articles.
- **HighlightAll** (boolean): if `true` the whole document will be used as the headline, ignoring the preceding three parameters. The default is `false`. 

Ranking can be expensive since it requires consulting the `tsvector` of each matching document, which can be I/O bound and therefore slow. Unfortunately, it is almost impossible to avoid since practical queries often result in large numbers of matches.
• **MaxFragments (integer):** maximum number of text fragments to display. The default value of zero selects a non-fragment-based headline generation method. A value greater than zero selects fragment-based headline generation (see below).

• **StartSel, StopSel (strings):** the strings with which to delimit query words appearing in the document, to distinguish them from other excerpted words. The default values are "\(<b>\)" and "\(</b>\)", which can be suitable for HTML output.

• **FragmentDelimiter (string):** When more than one fragment is displayed, the fragments will be separated by this string. The default is "...".

These option names are recognized case-insensitively. You must double-quote string values if they contain spaces or commas.

In non-fragment-based headline generation, `ts_headline` locates matches for the given query and chooses a single one to display, preferring matches that have more query words within the allowed headline length. In fragment-based headline generation, `ts_headline` locates the query matches and splits each match into “fragments” of no more than `MaxWords` words each, preferring fragments with more query words, and when possible “stretching” fragments to include surrounding words. The fragment-based mode is thus more useful when the query matches span large sections of the document, or when it’s desirable to display multiple matches. In either mode, if no query matches can be identified, then a single fragment of the first `MinWords` words in the document will be displayed.

For example:

```sql
SELECT ts_headline('english',
    'The most common type of search
is to find all documents containing given query terms
and return them in order of their similarity to the
query.',
    to Tsquery('english', 'query & similarity'));
```

`ts_headline` uses the original document, not a `tsvector` summary, so it can be slow and should be used with care.

### 12.4. Additional Features

This section describes additional functions and operators that are useful in connection with text search.

#### 12.4.1. Manipulating Documents

Section 12.3.1 showed how raw textual documents can be converted into `tsvector` values. Postgres Pro also provides functions and operators that can be used to manipulate documents that are already in `tsvector` form.
tsvector || tsvector

The tsvector concatenation operator returns a vector which combines the lexemes and positional information of the two vectors given as arguments. Positions and weight labels are retained during the concatenation. Positions appearing in the right-hand vector are offset by the largest position mentioned in the left-hand vector, so that the result is nearly equivalent to the result of performing to_tsvector on the concatenation of the two original document strings. (The equivalence is not exact, because any stop-words removed from the end of the left-hand argument will not affect the result, whereas they would have affected the positions of the lexemes in the right-hand argument if textual concatenation were used.)

One advantage of using concatenation in the vector form, rather than concatenating text before applying to_tsvector, is that you can use different configurations to parse different sections of the document. Also, because the setweight function marks all lexemes of the given vector the same way, it is necessary to parse the text and do setweight before concatenating if you want to label different parts of the document with different weights.

setweight(vector tsvector, weight "char") returns tsvector

setweight returns a copy of the input vector in which every position has been labeled with the given weight, either A, B, C, or D. (D is the default for new vectors and as such is not displayed on output.) These labels are retained when vectors are concatenated, allowing words from different parts of a document to be weighted differently by ranking functions.

Note that weight labels apply to positions, not lexemes. If the input vector has been stripped of positions then setweight does nothing.

length(vector tsvector) returns integer

Returns the number of lexemes stored in the vector.

strip(vector tsvector) returns tsvector

Returns a vector that lists the same lexemes as the given vector, but lacks any position or weight information. The result is usually much smaller than an unstripped vector, but it is also less useful. Relevance ranking does not work as well on stripped vectors as unstripped ones. Also, the <-> (FOLLOWED BY) tsquery operator will never match stripped input, since it cannot determine the distance between lexeme occurrences.

A full list of tsvector-related functions is available in Table 9.42.

12.4.2. Manipulating Queries

Section 12.3.2 showed how raw textual queries can be converted into tsquery values. Postgres Pro also provides functions and operators that can be used to manipulate queries that are already in tsquery form.

tsquery && tsquery

Returns the AND-combination of the two given queries.

tsquery || tsquery

Returns the OR-combination of the two given queries.

!! tsquery

Returns the negation (NOT) of the given query.

tsquery <-> tsquery

Returns a query that searches for a match to the first given query immediately followed by a match to the second given query, using the <-> (FOLLOWED BY) tsquery operator. For example:

```
SELECT to_tsquery('fat') <-> to_tsquery('cat | rat');
```
 FULL TEXT SEARCH

?column?
---------------------------------
'fat' <-> ( 'cat' | 'rat' )

tquery_phrase(query1 tsquery, query2 tsquery [, distance integer ]) returns tsquery

Returns a query that searches for a match to the first given query followed by a match to the second
given query at a distance of exactly distance lexemes, using the <N> tsquery operator. For example:

SELECT tquery_phrase(to_tquery('fat'), to_tquery('cat'), 10);

numnode(query tsquery) returns integer

Returns the number of nodes (lexemes plus operators) in a tsquery. This function is useful to
determine if the query is meaningful (returns > 0), or contains only stop words (returns 0). Examples:

SELECT numnode(plainto_tquery('the any'));
NOTICE:  query contains only stopword(s) or doesn't contain lexeme(s), ignored
numnode
--------
0

SELECT numnode('foo & bar'::tsquery);
numnode
--------
3

querytree(query tsquery) returns text

Returns the portion of a tsquery that can be used for searching an index. This function is useful for
detecting unindexable queries, for example those containing only stop words or only negated terms.
For example:

SELECT querytree(to_tquery('defined'));
querytree
--------
'defin'

SELECT querytree(to_tquery('!defined'));
querytree
--------
T

12.4.2.1. Query Rewriting

The ts_rewrite family of functions search a given tsquery for occurrences of a target subquery, and
replace each occurrence with a substitute subquery. In essence this operation is a tsquery-specific
version of substring replacement. A target and substitute combination can be thought of as a query
rewrite rule. A collection of such rewrite rules can be a powerful search aid. For example, you can
expand the search using synonyms (e.g., new york, big apple, nyc, gotham) or narrow the search
to direct the user to some hot topic. There is some overlap in functionality between this feature and
thesaurus dictionaries (Section 12.6.4). However, you can modify a set of rewrite rules on-the-fly without
reindexing, whereas updating a thesaurus requires reindexing to be effective.

ts_rewrite (query tsquery, target tsquery, substitute tsquery) returns tsquery

This form of ts_rewrite simply applies a single rewrite rule: target is replaced by substitute
wherever it appears in query. For example:

SELECT ts_rewrite('a & b':tsquery, 'a':tsquery, 'c':tsquery);
ts_rewrite (query tsquery, select text) returns tsquery

This form of ts_rewrite accepts a starting query and an SQL select command, which is given as a text string. The select must yield two columns of tsquery type. For each row of the select result, occurrences of the first column value (the target) are replaced by the second column value (the substitute) within the current query value. For example:

```sql
CREATE TABLE aliases (t tsquery PRIMARY KEY, s tsquery);
INSERT INTO aliases VALUES('a', 'c');

SELECT ts_rewrite('a & b'::tsquery, 'SELECT t,s FROM aliases');
```

Note that when multiple rewrite rules are applied in this way, the order of application can be important; so in practice you will want the source query to ORDER BY some ordering key.

Let's consider a real-life astronomical example. We'll expand query supernovae using table-driven rewriting rules:

```sql
CREATE TABLE aliases (t tsquery primary key, s tsquery);
INSERT INTO aliases VALUES(to_tsquery('supernovae'), to_tsquery('supernovae|sn'));

SELECT ts_rewrite(to_tsquery('supernovae & crab'), 'SELECT * FROM aliases');
```

We can change the rewriting rules just by updating the table:

```sql
UPDATE aliases
SET s = to_tsquery('supernovae|sn & !nebulae')
WHERE t = to_tsquery('supernovae');

SELECT ts_rewrite(to_tsquery('supernovae & crab'), 'SELECT * FROM aliases');
```

Rewriting can be slow when there are many rewriting rules, since it checks every rule for a possible match. To filter out obvious non-candidate rules we can use the containment operators for the tsquery type. In the example below, we select only those rules which might match the original query:

```sql
SELECT ts_rewrite('a & b'::tsquery, 'SELECT t,s FROM aliases WHERE ''a & b''::tsquery @> t>');
```

12.4.3. Triggers for Automatic Updates

Note

The method described in this section has been obsoleted by the use of stored generated columns, as described in Section 12.2.2.
When using a separate column to store the tsvector representation of your documents, it is necessary to create a trigger to update the tsvector column when the document content columns change. Two built-in trigger functions are available for this, or you can write your own.

```
tsvector_update_trigger(tsvector_column_name, config_name, text_column_name [, ... ])
tsvector_update_trigger_column(tsvector_column_name, config_column_name, text_column_name [, ... ])
```

These trigger functions automatically compute a tsvector column from one or more textual columns, under the control of parameters specified in the CREATE TRIGGER command. An example of their use is:

```
CREATE TABLE messages (  
  title       text,  
  body        text,  
  tsv         tsvector  
);

CREATE TRIGGER tsvectorupdate BEFORE INSERT OR UPDATE  
ON messages FOR EACH ROW EXECUTE FUNCTION  
tsvector_update_trigger(tsv, 'pg_catalog.english', title, body);

INSERT INTO messages VALUES('title here', 'the body text is here');

SELECT * FROM messages;

<table>
<thead>
<tr>
<th>title</th>
<th>body</th>
<th>tsv</th>
</tr>
</thead>
<tbody>
<tr>
<td>title here</td>
<td>the body text is here</td>
<td>'bodi':4 'text':5 'titl':1</td>
</tr>
</tbody>
</table>

SELECT title, body FROM messages WHERE tsv @@ to_tsquery('title & body');

<table>
<thead>
<tr>
<th>title</th>
<th>body</th>
</tr>
</thead>
<tbody>
<tr>
<td>title here</td>
<td>the body text is here</td>
</tr>
</tbody>
</table>

Having created this trigger, any change in title or body will automatically be reflected into tsv, without the application having to worry about it.

The first trigger argument must be the name of the tsvector column to be updated. The second argument specifies the text search configuration to be used for the conversion. For tsvector_update_trigger, the configuration name is simply given as the second trigger argument. It must be schema-qualified as shown above, so that the trigger behavior will not change with changes in search_path. For tsvector_update_trigger_column, the second trigger argument is the name of another table column, which must be of type regconfig. This allows a per-row selection of configuration to be made. The remaining argument(s) are the names of textual columns (of type text, varchar, or char). These will be included in the document in the order given. NULL values will be skipped (but the other columns will still be indexed).

A limitation of these built-in triggers is that they treat all the input columns alike. To process columns differently — for example, to weight title differently from body — it is necessary to write a custom trigger. Here is an example using PL/pgSQL as the trigger language:

```
CREATE FUNCTION messages_trigger() RETURNS trigger AS $$  
begin  
  new.tsv :=  
    setweight(to_tsvector('pg_catalog.english', coalesce(new.title,'')), 'A')  
  ||  
    setweight(to_tsvector('pg_catalog.english', coalesce(new.body,'')), 'D');  
  return new;  
end  
$$ LANGUAGE plpgsql;

CREATE TRIGGER tsvectorupdate BEFORE INSERT OR UPDATE
```
ON messages FOR EACH ROW EXECUTE FUNCTION messages_trigger();

Keep in mind that it is important to specify the configuration name explicitly when creating \texttt{tsvector} values inside triggers, so that the column's contents will not be affected by changes to \texttt{default_text_search_config}. Failure to do this is likely to lead to problems such as search results changing after a dump and reload.

\section*{12.4.4. Gathering Document Statistics}

The function \texttt{ts_stat} is useful for checking your configuration and for finding stop-word candidates.

\begin{verbatim}
ts_stat(sqlquery text, [ weights text, ]
        OUT word text, OUT ndoc integer,
        OUT nentry integer) returns setof record

sqlquery\texttt{ is a text value containing an SQL query which must return a single }\texttt{tsvector column. ts_stat executes the query and returns statistics about each distinct lexeme (word) contained in the tsvector data. The columns returned are}

\begin{itemize}
  \item \texttt{word text} — the value of a lexeme
  \item \texttt{ndoc integer} — number of documents (\texttt{tsvector}s) the word occurred in
  \item \texttt{nentry integer} — total number of occurrences of the word
\end{itemize}

If \texttt{weights} is supplied, only occurrences having one of those weights are counted.

For example, to find the ten most frequent words in a document collection:

\begin{verbatim}
SELECT * FROM ts_stat('SELECT vector FROM apod')
ORDER BY nentry DESC, ndoc DESC, word
LIMIT 10;
\end{verbatim}

The same, but counting only word occurrences with weight \texttt{A} or \texttt{B}:

\begin{verbatim}
SELECT * FROM ts_stat('SELECT vector FROM apod', 'ab')
ORDER BY nentry DESC, ndoc DESC, word
LIMIT 10;
\end{verbatim}

\section*{12.5. Parsers}

Text search parsers are responsible for splitting raw document text into \textit{tokens} and identifying each token's type, where the set of possible types is defined by the parser itself. Note that a parser does not modify the text at all — it simply identifies plausible word boundaries. Because of this limited scope, there is less need for application-specific custom parsers than there is for custom dictionaries. At present Postgres Pro provides just one built-in parser, which has been found to be useful for a wide range of applications.

The built-in parser is named \texttt{pg_catalog.default}. It recognizes 23 token types, shown in Table \ref{table:default-parsers}.

\begin{table}[h]
\centering
\begin{tabular}{|l|l|l|}
\hline
\textbf{Alias} & \textbf{Description} & \textbf{Example} \\
\hline
asciiword & Word, all ASCII letters & elephant \\
word & Word, all letters & mañana \\
umword & Word, letters and digits & beta1 \\
asciihword & Hyphenated word, all ASCII & up-to-date \\
hword & Hyphenated word, all letters & lógico-matemática \\
umhword & Hyphenated word, letters and digits & postgresql-beta1 \\
\hline
\end{tabular}
\caption{Default Parser's Token Types}
\end{table}

</tr>
</tbody>
</table>

### Note

The parser's notion of a “letter” is determined by the database’s locale setting, specifically `lc_ctype`. Words containing only the basic ASCII letters are reported as a separate token type, since it is sometimes useful to distinguish them. In most European languages, token types `word` and `asciword` should be treated alike.

`email` does not support all valid email characters as defined by [RFC 5322](https://tools.ietf.org/html/rfc5322). Specifically, the only non-alphanumeric characters supported for email user names are period, dash, and underscore.

It is possible for the parser to produce overlapping tokens from the same piece of text. As an example, a hyphenated word will be reported both as the entire word and as each component:

```sql
SELECT alias, description, token FROM ts_debug('foo-bar-beta1');
```

<table>
<thead>
<tr>
<th>alias</th>
<th>description</th>
<th>token</th>
</tr>
</thead>
<tbody>
<tr>
<td>numhword</td>
<td>Hyphenated word, letters and digits</td>
<td>foo-bar-beta1</td>
</tr>
<tr>
<td>hword_asciipart</td>
<td>Hyphenated word part, all ASCII</td>
<td>foo</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td>-</td>
</tr>
<tr>
<td>hword_asciipart</td>
<td>Hyphenated word part, all ASCII</td>
<td>bar</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td>-</td>
</tr>
<tr>
<td>hword_numpart</td>
<td>Hyphenated word part, letters and digits</td>
<td>beta1</td>
</tr>
</tbody>
</table>

This behavior is desirable since it allows searches to work for both the whole compound word and for components. Here is another instructive example:

```sql
SELECT alias, description, token FROM ts_debug('http://example.com/stuff/index.html');
```
### 12.6. Dictionaries

Dictionaries are used to eliminate words that should not be considered in a search (*stop words*), and to normalize words so that different derived forms of the same word will match. A successfully normalized word is called a *lexeme*. Aside from improving search quality, normalization and removal of stop words reduce the size of the *tsvector* representation of a document, thereby improving performance. Normalization does not always have linguistic meaning and usually depends on application semantics.

Some examples of normalization:

- Linguistic — *Ispell* dictionaries try to reduce input words to a normalized form; stemmer dictionaries remove word endings
- URL locations can be canonicalized to make equivalent URLs match:
  - http://www.pgsql.ru/db/mw/index.html
  - http://www.pgsql.ru/db/mw/
  - http://www.pgsql.ru/db/../db/mw/index.html
- Color names can be replaced by their hexadecimal values, e.g., red, green, blue, magenta → FF0000, 00FF00, 0000FF, FF00FF
- If indexing numbers, we can remove some fractional digits to reduce the range of possible numbers, so for example 3.14159265359, 3.1415926, 3.14 will be the same after normalization if only two digits are kept after the decimal point.

A dictionary is a program that accepts a token as input and returns:

- an array of lexemes if the input token is known to the dictionary (notice that one token can produce more than one lexeme)
- a single lexeme with the `TSL_FILTER` flag set, to replace the original token with a new token to be passed to subsequent dictionaries (a dictionary that does this is called a *filtering dictionary*)
- an empty array if the dictionary knows the token, but it is a stop word
- `NULL` if the dictionary does not recognize the input token

Postgres Pro provides predefined dictionaries for many languages. There are also several predefined templates that can be used to create new dictionaries with custom parameters. Each predefined dictionary template is described below. If no existing template is suitable, it is possible to create new ones; see the *contrib/* area of the Postgres Pro distribution for examples.

A text search configuration binds a parser together with a set of dictionaries to process the parser's output tokens. For each token type that the parser can return, a separate list of dictionaries is specified by the configuration. When a token of that type is found by the parser, each dictionary in the list is consulted in turn, until some dictionary recognizes it as a known word. If it is identified as a stop word, or if no dictionary recognizes the token, it will be discarded and not indexed or searched for. Normally, the first dictionary that returns a non-`NULL` output determines the result, and any remaining dictionaries are not consulted; but a filtering dictionary can replace the given word with a modified word, which is then passed to subsequent dictionaries.

The general rule for configuring a list of dictionaries is to place first the most narrow, most specific dictionary, then the more general dictionaries, finishing with a very general dictionary, like a Snowball stemmer or `simple`, which recognizes everything. For example, for an astronomy-specific search (`astro_en` configuration) one could bind token type `asciword` (ASCII word) to a synonym dictionary of astronomical terms, a general English dictionary and a Snowball English stemmer:

```sql
ALTER TEXT SEARCH CONFIGURATION astro_en
  ADD MAPPING FOR asciword WITH astrosyn, english_ispell, english_stem;
```
A filtering dictionary can be placed anywhere in the list, except at the end where it'd be useless. Filtering dictionaries are useful to partially normalize words to simplify the task of later dictionaries. For example, a filtering dictionary could be used to remove accents from accented letters, as is done by the unaccent module.

### 12.6.1. Stop Words

Stop words are words that are very common, appear in almost every document, and have no discrimination value. Therefore, they can be ignored in the context of full text searching. For example, every English text contains words like a and the, so it is useless to store them in an index. However, stop words do affect the positions in \texttt{tsvector}, which in turn affect ranking:

```sql
SELECT to_tsvector('english', 'in the list of stop words');
```

\texttt{to_tsvector}

```sql
'list':3 'stop':5 'word':6
```

The missing positions 1, 2, 4 are because of stop words. Ranks calculated for documents with and without stop words are quite different:

```sql
SELECT ts_rank_cd (to_tsvector('english', 'in the list of stop words'),
    to_tsquery('list & stop'));
```

\texttt{ts_rank_cd}

```sql
0.05
```

```sql
SELECT ts_rank_cd (to_tsvector('english', 'list stop words'), to_tsquery('list &
    stop'));
```

\texttt{ts_rank_cd}

```sql
0.1
```

It is up to the specific dictionary how it treats stop words. For example, ispell dictionaries first normalize words and then look at the list of stop words, while Snowball stemmers first check the list of stop words. The reason for the different behavior is an attempt to decrease noise.

### 12.6.2. Simple Dictionary

The simple dictionary template operates by converting the input token to lower case and checking it against a file of stop words. If it is found in the file then an empty array is returned, causing the token to be discarded. If not, the lower-cased form of the word is returned as the normalized lexeme. Alternatively, the dictionary can be configured to report non-stop-words as unrecognized, allowing them to be passed on to the next dictionary in the list.

Here is an example of a dictionary definition using the simple template:

```sql
CREATE TEXT SEARCH DICTIONARY public.simple_dict (
    TEMPLATE = pg_catalog.simple,
    STOPWORDS = english
);
```

Here, \texttt{english} is the base name of a file of stop words. The file's full name will be $\$\text{SHAREDIR/}
\text{tsearch_data/english.stop}$, where $\$\text{SHAREDIR}$ means the Postgres Pro installation's shared-data directory, often `/usr/local/share/postgresql` (use `pg_config --sharedir` to determine it if you're not sure). The file format is simply a list of words, one per line. Blank lines and trailing spaces are ignored, and upper case is folded to lower case, but no other processing is done on the file contents.

Now we can test our dictionary:

```sql
SELECT ts_lexize('public.simple_dict', 'YeS');
```

\texttt{ts_lexize}

```sql
'395'
```
SELECT ts_lexize('public.simple_dict', 'The');

We can also choose to return NULL, instead of the lower-cased word, if it is not found in the stop words file. This behavior is selected by setting the dictionary's Accept parameter to false. Continuing the example:

ALTER TEXT SEARCH DICTIONARY public.simple_dict ( Accept = false );

SELECT ts_lexize('public.simple_dict', 'YeS');

With the default setting of Accept = true, it is only useful to place a simple dictionary at the end of a list of dictionaries, since it will never pass on any token to a following dictionary. Conversely, Accept = false is only useful when there is at least one following dictionary.

**Caution**

Most types of dictionaries rely on configuration files, such as files of stop words. These files must be stored in UTF-8 encoding. They will be translated to the actual database encoding, if that is different, when they are read into the server.

**Caution**

Normally, a database session will read a dictionary configuration file only once, when it is first used within the session. If you modify a configuration file and want to force existing sessions to pick up the new contents, issue an ALTER TEXT SEARCH DICTIONARY command on the dictionary. This can be a “dummy” update that doesn't actually change any parameter values.

### 12.6.3. Synonym Dictionary

This dictionary template is used to create dictionaries that replace a word with a synonym. Phrases are not supported (use the thesaurus template (Section 12.6.4) for that). A synonym dictionary can be used to overcome linguistic problems, for example, to prevent an English stemmer dictionary from reducing the word “Paris” to “pari”. It is enough to have a Paris paris line in the synonym dictionary and put it before the english.stem dictionary. For example:

```
SELECT * FROM ts_debug('english', 'Paris');

CREATE TEXT SEARCH DICTIONARY my_synonym (
    TEMPLATE = synonym,
    SYNONYMS = my_synonyms
);`
ALTER TEXT SEARCH CONFIGURATION english

ALTER MAPPING FOR asciiword
WITH my_synonym, english_stem;

SELECT * FROM ts_debug('english', 'Paris');

<table>
<thead>
<tr>
<th>alias</th>
<th>description</th>
<th>token</th>
<th>dictionaries</th>
<th>dictionary</th>
</tr>
</thead>
<tbody>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>Paris</td>
<td>{my_synonym,english_stem}</td>
<td>my_synonym</td>
</tr>
</tbody>
</table>

The only parameter required by the **synonym** template is `SYNONYMS`, which is the base name of its configuration file — `my_synonyms` in the above example. The file's full name will be `$SHAREDIR/tsearch_data/my_synonyms.syn` (where `$SHAREDIR` means the Postgres Pro installation's shared-data directory). The file format is just one line per word to be substituted, with the word followed by its synonym, separated by white space. Blank lines and trailing spaces are ignored.

The **synonym** template also has an optional parameter `CaseSensitive`, which defaults to `false`. When `CaseSensitive` is `false`, words in the synonym file are folded to lower case, as are input tokens. When it is `true`, words and tokens are not folded to lower case, but are compared as-is.

An asterisk (*) can be placed at the end of a synonym in the configuration file. This indicates that the synonym is a prefix. The asterisk is ignored when the entry is used in `to_tsvector()`, but when it is used in `to_tsquery()`, the result will be a query item with the prefix match marker (see Section 12.3.2). For example, suppose we have these entries in `$SHAREDIR/tsearch_data/synonym_sample.syn`:

```
postgres        pgsql
postgresql      pgsql
postgre pgsql
google googl
indices index*
```

Then we will get these results:

```
mydb=# CREATE TEXT SEARCH DICTIONARY syn (template=synonym, synonyms='synonym_sample');
mydb=# SELECT ts_lexize('syn', 'indices');
  ts_lexize
  -------
     {index}
  (1 row)

mydb=# CREATE TEXT SEARCH CONFIGURATION tst (copy=simple);
mydb=# ALTER TEXT SEARCH CONFIGURATION tst ALTER MAPPING FOR asciiword WITH syn;
mydb=# SELECT to_tsvector('tst', 'indices');
  to_tsvector
  -------
     'index':1
  (1 row)

mydb=# SELECT to_tsquery('tst', 'indices');
  to_tsquery
  -------
     'index':*
  (1 row)

mydb=# SELECT 'indexes are very useful'::tsvector;
  tsvector
  ------------------
     'are' 'indexes' 'useful' 'very'
```

397
mydb=# SELECT 'indexes are very useful'::tsvector @@ to_tsquery('tst', 'indices');

<table>
<thead>
<tr>
<th>?column?</th>
</tr>
</thead>
<tbody>
<tr>
<td>t</td>
</tr>
</tbody>
</table>

(1 row)

12.6.4. Thesaurus Dictionary

A thesaurus dictionary (sometimes abbreviated as TZ) is a collection of words that includes information about the relationships of words and phrases, i.e., broader terms (BT), narrower terms (NT), preferred terms, non-preferred terms, related terms, etc.

Basically a thesaurus dictionary replaces all non-preferred terms by one preferred term and, optionally, preserves the original terms for indexing as well. Postgres Pro's current implementation of the thesaurus dictionary is an extension of the synonym dictionary with added phrase support. A thesaurus dictionary requires a configuration file of the following format:

```
# this is a comment
sample word(s) : indexed word(s)
more sample word(s) : more indexed word(s)
...
```

where the colon (:) symbol acts as a delimiter between a phrase and its replacement.

A thesaurus dictionary uses a subdictionary (which is specified in the dictionary's configuration) to normalize the input text before checking for phrase matches. It is only possible to select one subdictionary. An error is reported if the subdictionary fails to recognize a word. In that case, you should remove the use of the word or teach the subdictionary about it. You can place an asterisk (*) at the beginning of an indexed word to skip applying the subdictionary to it, but all sample words must be known to the subdictionary.

The thesaurus dictionary chooses the longest match if there are multiple phrases matching the input, and ties are broken by using the last definition.

Specific stop words recognized by the subdictionary cannot be specified; instead use ? to mark the location where any stop word can appear. For example, assuming that a and the are stop words according to the subdictionary:

```
? one ? two : swsw
matches a one the two and the one a two; both would be replaced by swsw.
```

Since a thesaurus dictionary has the capability to recognize phrases it must remember its state and interact with the parser. A thesaurus dictionary uses these assignments to check if it should handle the next word or stop accumulation. The thesaurus dictionary must be configured carefully. For example, if the thesaurus dictionary is assigned to handle only the asciiword token, then a thesaurus dictionary definition like `one 7` will not work since token type `uint` is not assigned to the thesaurus dictionary.

Caution

Thesauruses are used during indexing so any change in the thesaurus dictionary's parameters requires reindexing. For most other dictionary types, small changes such as adding or removing stopwords does not force reindexing.

12.6.4.1. Thesaurus Configuration

To define a new thesaurus dictionary, use the thesaurus template. For example:

```
CREATE TEXT SEARCH DICTIONARY thesaurus_simple (}
```
Here:

- thesaurus_simple is the new dictionary's name
- mythesaurus is the base name of the thesaurus configuration file. (Its full name will be $SHAREDIR/tsearch_data/mythesaurus.ths, where $SHAREDIR means the installation shared-data directory.)
- pg_catalog.english_stem is the subdictionary (here, a Snowball English stemmer) to use for thesaurus normalization. Notice that the subdictionary will have its own configuration (for example, stop words), which is not shown here.

Now it is possible to bind the thesaurus dictionary thesaurus_simple to the desired token types in a configuration, for example:

```
ALTER TEXT SEARCH CONFIGURATION russian
  ALTER MAPPING FOR asciiword, asciihword, hword_asciipart
    WITH thesaurus_simple;
```

### 12.6.4.2. Thesaurus Example

Consider a simple astronomical thesaurus thesaurus_astro, which contains some astronomical word combinations:

```
supernovae stars : sn
crab nebulae : crab
```

Below we create a dictionary and bind some token types to an astronomical thesaurus and English stemmer:

```
CREATE TEXT SEARCH DICTIONARY thesaurus_astro (  
  TEMPLATE = thesaurus,
  DictFile = thesaurus_astro,
  Dictionary = english_stem
);  
ALTER TEXT SEARCH CONFIGURATION russian
  ALTER MAPPING FOR asciiword, asciihword, hword_asciipart
    WITH thesaurus_astro, english_stem;
```

Now we can see how it works. `ts_lexize` is not very useful for testing a thesaurus, because it treats its input as a single token. Instead we can use `plainto_tsquery` and `to_tsvector` which will break their input strings into multiple tokens:

```
SELECT plainto_tsquery('supernova star');
plainto_tsquery
---------
'sn'

SELECT to_tsvector('supernova star');
to_tsvector
---------
'sn':1
```

In principle, one can use `to_tsquery` if you quote the argument:

```
SELECT to_tsquery('''supernova star''');
to_tsquery
---------
'sn'
```

Notice that supernova star matches supernovae stars in thesaurus_astro because we specified the english_stem stemmer in the thesaurus definition. The stemmer removed the e and s.
To index the original phrase as well as the substitute, just include it in the right-hand part of the definition:

```
select plainto_tsquery('supernova star');
```

-----------------------------
'sn' & 'supernova' & 'star'

### 12.6.5. Ispell Dictionary

The Ispell dictionary template supports *morphological dictionaries*, which can normalize many different linguistic forms of a word into the same lexeme. For example, an English Ispell dictionary can match all declensions and conjugations of the search term `bank`, e.g., `banking`, `banked`, `banks`, `banks'`, and `bank's`.

The standard Postgres Pro distribution does not include any Ispell configuration files. Dictionaries for a large number of languages are available from Ispell. Also, some more modern dictionary file formats are supported — MySpell (OO < 2.0.1) and Hunspell (OO >= 2.0.2). A large list of dictionaries is available on the [OpenOffice Wiki](https://wiki.openoffice.org/wiki/Dictionary).

To create an Ispell dictionary perform these steps:

- download dictionary configuration files. OpenOffice extension files have the `.oxt` extension. It is necessary to extract `.aff` and `.dic` files, change extensions to `.affix` and `.dict`. For some dictionary files it is also needed to convert characters to the UTF-8 encoding with commands (for example, for a Norwegian language dictionary):

  ```
  iconv -f ISO_8859-1 -t UTF-8 -o nn_no.affix nn_NO.aff
  iconv -f ISO_8859-1 -t UTF-8 -o nn_no.dic nn_NO.dic
  ```

- copy files to the `$SHAREDIR/tsearch_data` directory
- load files into Postgres Pro with the following command:

  ```
  CREATE TEXT SEARCH DICTIONARY english_hunspell (
    TEMPLATE = ispell,
    DictFile = en_us,
    AffFile = en_us,
    Stopwords = english);
  ```

Here, DictFile, AffFile, and StopWords specify the base names of the dictionary, affixes, and stop-words files. The stop-words file has the same format explained above for the simple dictionary type. The format of the other files is not specified here but is available from the above-mentioned web sites.

Ispell dictionaries usually recognize a limited set of words, so they should be followed by another broader dictionary; for example, a Snowball dictionary, which recognizes everything.

The `.affix` file of Ispell has the following structure:

```
prefixes
flag *A:
  > RE      # As in enter > reenter
suffixes
flag T:
  E           >   ST      # As in late > latest
  [^AEIOU]Y   >   -Y,IEST  # As in dirty > dirtiest
  [AEIOU]Y    >   EST     # As in gray > grayest
  [^EY]       >   EST     # As in small > smallest
```

And the `.dict` file has the following structure:

```
lapse/ADGRS
lard/DGRS
```
Format of the `.dict` file is:

`basic_form/affix_class_name`

In the `.affix` file every affix flag is described in the following format:

`condition > [-stripping_letters,] adding_affix`

Here, `condition` has a format similar to the format of regular expressions. It can use groupings ` [... ]` and `[^... ]`. For example, `[^AI]ou` means that the last letter of the word is "y" and the penultimate letter is "a", "e", "i", "o" or "u". `[^EY]` means that the last letter is neither "e" nor "y".

Ispell dictionaries support splitting compound words; a useful feature. Notice that the affix file should specify a special flag using the `compoundwords controlled` statement that marks dictionary words that can participate in compound formation:

```
compoundwords controlled z
```

Here are some examples for the Norwegian language:

```
SELECT ts_lexize('norwegian_ispell', 'overbuljongterningpakkmesterassistent');
{over,buljong,terning,pakk,mester,assistent}
```

```
SELECT ts_lexize('norwegian_ispell', 'sjokoladefabrikk');
{sjokoladefabrikk,sjokolade,fabrikk}
```

MySpell format is a subset of Hunspell. The `.affix` file of Hunspell has the following structure:

```
PFX A Y 1
PFX A 0 re
SFX T N 4
SFX T 0 st
t SFX T y iest [^aeiou]y
SFX T 0 est [aeiou]y
SFX T 0 est [^ey]
```

The first line of an affix class is the header. Fields of an affix rules are listed after the header:

- parameter name (PFX or SFX)
- flag (name of the affix class)
- stripping characters from beginning (at prefix) or end (at suffix) of the word
- adding affix
- condition that has a format similar to the format of regular expressions.

The `.dict` file looks like the `.dict` file of Ispell:

```
larder/M
lardy/RT
large/RSPMYT
largehearted
```

### Note

MySpell does not support compound words. Hunspell has sophisticated support for compound words. At present, Postgres Pro implements only the basic compound word operations of Hunspell.

### 12.6.6. Snowball Dictionary

The Snowball dictionary template is based on a project by Martin Porter, inventor of the popular Porter's stemming algorithm for the English language. Snowball now provides stemming algorithms for many...
languages (see the Snowball site for more information). Each algorithm understands how to reduce common variant forms of words to a base, or stem, spelling within its language. A Snowball dictionary requires a language parameter to identify which stemmer to use, and optionally can specify a stopword file name that gives a list of words to eliminate. (Postgres Pro's standard stopword lists are also provided by the Snowball project.) For example, there is a built-in definition equivalent to

```
CREATE TEXT SEARCH DICTIONARY english_stem (
    TEMPLATE = snowball,
    Language = english,
    StopWords = english
);
```

The stopword file format is the same as already explained.

A Snowball dictionary recognizes everything, whether or not it is able to simplify the word, so it should be placed at the end of the dictionary list. It is useless to have it before any other dictionary because a token will never pass through it to the next dictionary.

### 12.7. Configuration Example

A text search configuration specifies all options necessary to transform a document into a `tsvector`: the parser to use to break text into tokens, and the dictionaries to use to transform each token into a lexeme. Every call of `to_tsvector` or `to_tsquery` needs a text search configuration to perform its processing. The configuration parameter `default_text_search_config` specifies the name of the default configuration, which is the one used by text search functions if an explicit configuration parameter is omitted. It can be set in `postgresql.conf`, or set for an individual session using the `SET` command.

Several predefined text search configurations are available, and you can create custom configurations easily. To facilitate management of text search objects, a set of SQL commands is available, and there are several `psql` commands that display information about text search objects (Section 12.10).

As an example we will create a configuration `pg`, starting by duplicating the built-in `english` configuration:

```
CREATE TEXT SEARCH CONFIGURATION public.pg ( COPY = pg_catalog.english );
```

We will use a Postgres Pro-specific synonym list and store it in `$SHAREDIR/tsearch_data/pg_dict.syn`. The file contents look like:

```
postgres    pg
pgsql       pg
postgresql  pg
```

We define the synonym dictionary like this:

```
CREATE TEXT SEARCH DICTIONARY pg_dict (  
    TEMPLATE = synonym,
    SYNONYMS = pg_dict
);
```

Next we register the Ispell dictionary `english_ispell`, which has its own configuration files:

```
CREATE TEXT SEARCH DICTIONARY english_ispell (  
    TEMPLATE = ispell,
    DictFile = english,
    AffFile = english,
    StopWords = english
);
```

Now we can set up the mappings for words in configuration `pg`:

```
ALTER TEXT SEARCH CONFIGURATION pg
    ALTER MAPPING FOR asciword, asciihword, hword_ascipart,
```
We choose not to index or search some token types that the built-in configuration does handle:

```sql
ALTER TEXT SEARCH CONFIGURATION pg
   DROP MAPPING FOR email, url, url_path, sfloat, float;
```

Now we can test our configuration:

```sql
SELECT * FROM ts_debug('public.pg', 'Postgres Pro, the highly scalable, SQL compliant, open source object-relational
database management system, is now undergoing beta testing of the next
version of our software.');
```

The next step is to set the session to use the new configuration, which was created in the `public` schema:

```sql
=> \dF
```

<table>
<thead>
<tr>
<th>Schema</th>
<th>Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>public</td>
<td>pg</td>
<td></td>
</tr>
</tbody>
</table>

```sql
SET default_text_search_config = 'public.pg';
SET SHOW default_text_search_config;
```

12.8. Testing and Debugging Text Search

The behavior of a custom text search configuration can easily become confusing. The functions described in this section are useful for testing text search objects. You can test a complete configuration, or test parsers and dictionaries separately.

12.8.1. Configuration Testing

The function `ts_debug` allows easy testing of a text search configuration.

```sql
ts_debug([ config regconfig, ] document text,
   OUT alias text,
   OUT description text,
   OUT token text,
   OUT dictionaries regdictionary[],
   OUT dictionary regdictionary,
   OUT lexemes text[])
returns setof record
```

`ts_debug` displays information about every token of `document` as produced by the parser and processed by the configured dictionaries. It uses the configuration specified by `config`, or `default_text_search_config` if that argument is omitted.

`ts_debug` returns one row for each token identified in the text by the parser. The columns returned are:

- `alias text` — short name of the token type
- `description text` — description of the token type
- `token text` — text of the token
**Full Text Search**

- `dictionaries regdictionary[]` — the dictionaries selected by the configuration for this token type
- `dictionary regdictionary` — the dictionary that recognized the token, or `NULL` if none did
- `lexemes text[]` — the lexeme(s) produced by the dictionary that recognized the token, or `NULL` if none did; an empty array `({})` means it was recognized as a stop word

Here is a simple example:

```sql
SELECT * FROM ts_debug('english', 'a fat cat sat on a mat - it ate a fat rats');
```

<table>
<thead>
<tr>
<th>alias</th>
<th>description</th>
<th>token</th>
<th>dictionaries</th>
<th>dictionary</th>
<th>lexemes</th>
</tr>
</thead>
<tbody>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>a</td>
<td>{english_stem}</td>
<td>english_stem</td>
<td>{}</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>

<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>it</td>
<td>{english_stem}</td>
<td>english_stem</td>
<td>{}</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>ate</td>
<td>{english_stem}</td>
<td>english_stem</td>
<td>{ate}</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>a</td>
<td>{english_stem}</td>
<td>english_stem</td>
<td>{}</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>fat</td>
<td>{english_stem}</td>
<td>english_stem</td>
<td>{fat}</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

For a more extensive demonstration, we first create a `public.english` configuration and Ispell dictionary for the English language:

```sql
CREATE TEXT SEARCH CONFIGURATION public.english ( COPY = pg_catalog.english );
CREATE TEXT SEARCH DICTIONARY english_ispell (  
    TEMPLATE = ispell,  
    DictFile = english,  
    AffFile = english,  
    StopWords = english
);
ALTER TEXT SEARCH CONFIGURATION public.english
    ALTER MAPPING FOR asciiword WITH english_ispell, english_stem;
SELECT * FROM ts_debug('public.english', 'The Brightest supernovaes');
```

<table>
<thead>
<tr>
<th>alias</th>
<th>description</th>
<th>token</th>
<th>dictionaries</th>
<th>dictionary</th>
<th>lexemes</th>
</tr>
</thead>
<tbody>
<tr>
<td>asciiword</td>
<td>Word, all ASCII</td>
<td>The</td>
<td>{english_ispell,english_stem}</td>
<td>english_ispell</td>
<td>{}</td>
</tr>
<tr>
<td>blank</td>
<td>Space symbols</td>
<td></td>
<td>{}</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

404
asciiword | Word, all ASCII | Brightest   | {english_ispell,english_stem} |
english_ispell | {bright}   
blank     | Space symbols   | {}             |
| asciiword | Word, all ASCII | supernovaes | {english_ispell,english_stem} |
english_stem   | {supernova}   

In this example, the word **Brightest** was recognized by the parser as an ASCII word (**asciiword**). For this token type the dictionary list is **english_ispell** and **english_stem**. The word was recognized by **english_ispell**, which reduced it to the noun **bright**. The word **supernovaes** is unknown to the **english_ispell** dictionary so it was passed to the next dictionary, and, fortunately, was recognized (in fact, **english_stem** is a Snowball dictionary which recognizes everything; that is why it was placed at the end of the dictionary list).

The word **The** was recognized by the **english_ispell** dictionary as a stop word (**Section 12.6.1**) and will not be indexed. The spaces are discarded too, since the configuration provides no dictionaries at all for them.

You can reduce the width of the output by explicitly specifying which columns you want to see:

```
SELECT alias, token, dictionary, lexemes
FROM ts_debug('public.english', 'The Brightest supernovaes');
```

```
<table>
<thead>
<tr>
<th>alias</th>
<th>token</th>
<th>dictionary</th>
<th>lexemes</th>
</tr>
</thead>
<tbody>
<tr>
<td>asciiword</td>
<td>The</td>
<td>english_ispell</td>
<td>{}</td>
</tr>
<tr>
<td>blank</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>Brightest</td>
<td>english_ispell</td>
<td>{bright}</td>
</tr>
<tr>
<td>blank</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>asciiword</td>
<td>supernovaes</td>
<td>english_stem</td>
<td>{supernova}</td>
</tr>
</tbody>
</table>
```

### 12.8.2. Parser Testing

The following functions allow direct testing of a text search parser.

```
ts_parse(parser_name text, document text, 
            OUT tokid integer, OUT token text) returns setof record
```

```
ts_parse(parser_oid oid, document text, 
            OUT tokid integer, OUT token text) returns setof record
```

**ts_parse** parses the given **document** and returns a series of records, one for each token produced by parsing. Each record includes a **tokid** showing the assigned token type and a **token** which is the text of the token. For example:

```
SELECT * FROM ts_parse('default', '123 - a number');
```

```
tokid | token
-------+--------
 22 | 123
 12 |
 12 | -
  1 | a
 12 |
  1 | number
```

```
ts_token_type(parser_name text, OUT tokid integer, 
               OUT alias text, OUT description text) returns setof record
```

```
ts_token_type(parser_oid oid, OUT tokid integer, 
               OUT alias text, OUT description text) returns setof record
```

**ts_token_type** returns a table which describes each type of token the specified parser can recognize. For each token type, the table gives the integer **tokid** that the parser uses to label a token of that type, the **alias** that names the token type in configuration commands, and a short **description**. For example:
SELECT * FROM ts_token_type('default');

<table>
<thead>
<tr>
<th>tokid</th>
<th>alias</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>asciiword</td>
<td>Word, all ASCII</td>
</tr>
<tr>
<td>2</td>
<td>word</td>
<td>Word, all letters</td>
</tr>
<tr>
<td>3</td>
<td>numword</td>
<td>Word, letters and digits</td>
</tr>
<tr>

</tr>
<tr>
<td>20</td>
<td>float</td>
<td>Decimal notation</td>
</tr>
<tr>
<td>21</td>
<td>int</td>
<td>Signed integer</td>
</tr>
<tr>
<td>22</td>
<td>uint</td>
<td>Unsigned integer</td>
</tr>
<tr>
<td>23</td>
<td>entity</td>
<td>XML entity</td>
</tr>
</tbody>
</table>

### 12.8.3. Dictionary Testing

The `ts_lexize` function facilitates dictionary testing.

\[
\text{ts_lexize(dict regdictionary, token text) returns text[]}\]

`ts_lexize` returns an array of lexemes if the input `token` is known to the dictionary, or an empty array if the token is known to the dictionary but it is a stop word, or `NULL` if it is an unknown word.

Examples:

```sql
SELECT ts_lexize('english_stem', 'stars');
```

```
{star}
```

```sql
SELECT ts_lexize('english_stem', 'a');
```

```
{}  
```

### Note

The `ts_lexize` function expects a single `token`, not text. Here is a case where this can be confusing:

```sql
SELECT ts_lexize('thesaurus_astro', 'supernovae stars') is null;
```

```
?column?
```

The thesaurus dictionary `thesaurus_astro` does know the phrase `supernovae stars`, but `ts_lexize` fails since it does not parse the input text but treats it as a single token. Use `plainto_tsquery` or `to_tsvector` to test thesaurus dictionaries, for example:
12.9. GIN and GiST Index Types

There are two kinds of indexes that can be used to speed up full text searches. Note that indexes are not mandatory for full text searching, but in cases where a column is searched on a regular basis, an index is usually desirable.

CREATE INDEX name ON table USING GIN (column);

Creates a GIN (Generalized Inverted Index)-based index. The column must be of tsvector type.

CREATE INDEX name ON table USING GIST (column [ { DEFAULT | tsvector_ops } (siglen = number) ]);

Creates a GiST (Generalized Search Tree)-based index. The column can be of tsvector or tsquery type. Optional integer parameter siglen determines signature length in bytes (see below for details).

GIN indexes are the preferred text search index type. As inverted indexes, they contain an index entry for each word (lexeme), with a compressed list of matching locations. Multi-word searches can find the first match, then use the index to remove rows that are lacking additional words. GIN indexes store only the words (lexemes) of tsvector values, and not their weight labels. Thus a table row recheck is needed when using a query that involves weights.

A GiST index is lossy, meaning that the index might produce false matches, and it is necessary to check the actual table row to eliminate such false matches. (Postgres Pro does this automatically when needed.) GiST indexes are lossy because each document is represented in the index by a fixed-length signature. The signature length in bytes is determined by the value of the optional integer parameter siglen. The default signature length (when siglen is not specified) is 124 bytes, the maximum signature length is 2024 bytes. The signature is generated by hashing each word into a single bit in an n-bit string, with all these bits OR-ed together to produce an n-bit document signature. When two words hash to the same bit position there will be a false match. If all words in the query have matches (real or false) then the table row must be retrieved to see if the match is correct. Longer signatures lead to a more precise search (scanning a smaller fraction of the index and fewer heap pages), at the cost of a larger index.

A GiST index can be covering, i.e., use the INCLUDE clause. Included columns can have data types without any GiST operator class. Included attributes will be stored uncompressed.

Lossiness causes performance degradation due to unnecessary fetches of table records that turn out to be false matches. Since random access to table records is slow, this limits the usefulness of GiST indexes. The likelihood of false matches depends on several factors, in particular the number of unique words, so using dictionaries to reduce this number is recommended.

Note that GIN index build time can often be improved by increasing maintenance_work_mem, while GiST index build time is not sensitive to that parameter.

Partitioning of big collections and the proper use of GIN and GiST indexes allows the implementation of very fast searches with online update. Partitioning can be done at the database level using table inheritance, or by distributing documents over servers and collecting external search results, e.g., via Foreign Data access. The latter is possible because ranking functions use only local information.

12.10. psql Support

Information about text search configuration objects can be obtained in psql using a set of commands:

\dF{d,p,t}[+][PATTERN]
An optional + produces more details.

The optional parameter PATTERN can be the name of a text search object, optionally schema-qualified. If PATTERN is omitted then information about all visible objects will be displayed. PATTERN can be a regular expression and can provide separate patterns for the schema and object names. The following examples illustrate this:

```sql
=> \dF *fulltext*
List of text search configurations
Schema | Name        | Description
--------+--------------+-------------
public | fulltext_cfg |

=> \dF *.fulltext*
List of text search configurations
Schema | Name        | Description
--------+--------------+-------------
fulltext | fulltext_cfg |
public | fulltext_cfg |
```

The available commands are:

```sql
\dF[+] [PATTERN]
List text search configurations (add + for more detail).

=> \dF russian
List of text search configurations
Schema | Name        | Description
--------+--------------+-------------
pg_catalog | russian | configuration for russian language

=> \dF+ russian
Text search configuration "pg_catalog.russian"
Parser: "pg_catalog.default"

12.11. Limitations

The current limitations of Postgres Pro's text search features are:

- The length of each lexeme must be less than 2 kilobytes
- The length of a tsvector (lexemes + positions) must be less than 1 megabyte
- The number of lexemes must be less than $2^{64}$
- Position values in tsvector must be greater than 0 and no more than 16,383
- The match distance in a $<N>$ (FOLLOWED BY) tsquery operator cannot be more than 16,384
- No more than 256 positions per lexeme
- The number of nodes (lexemes + operators) in a tsquery must be less than 32,768

For comparison, the PostgreSQL 8.1 documentation contained 10,441 unique words, a total of 335,420 words, and the most frequent word “postgresql” was mentioned 6,127 times in 655 documents.

Another example — the PostgreSQL mailing list archives contained 910,989 unique words with 57,491,343 lexemes in 461,020 messages.
Chapter 13. Concurrency Control

This chapter describes the behavior of the Postgres Pro database system when two or more sessions try to access the same data at the same time. The goals in that situation are to allow efficient access for all sessions while maintaining strict data integrity. Every developer of database applications should be familiar with the topics covered in this chapter.

13.1. Introduction

Postgres Pro provides a rich set of tools for developers to manage concurrent access to data. Internally, data consistency is maintained by using a multiversion model (Multiversion Concurrency Control, MVCC). This means that each SQL statement sees a snapshot of data (a database version) as it was some time ago, regardless of the current state of the underlying data. This prevents statements from viewing inconsistent data produced by concurrent transactions performing updates on the same data rows, providing transaction isolation for each database session. MVCC, by eschewing the locking methodologies of traditional database systems, minimizes lock contention in order to allow for reasonable performance in multiuser environments.

The main advantage of using the MVCC model of concurrency control rather than locking is that in MVCC locks acquired for querying (reading) data do not conflict with locks acquired for writing data, and so reading never blocks writing and writing never blocks reading. Postgres Pro maintains this guarantee even when providing the strictest level of transaction isolation through the use of an innovative Serializable Snapshot Isolation (SSI) level.

Table- and row-level locking facilities are also available in Postgres Pro for applications which don't generally need full transaction isolation and prefer to explicitly manage particular points of conflict. However, proper use of MVCC will generally provide better performance than locks. In addition, application-defined advisory locks provide a mechanism for acquiring locks that are not tied to a single transaction.

13.2. Transaction Isolation

The SQL standard defines four levels of transaction isolation. The most strict is Serializable, which is defined by the standard in a paragraph which says that any concurrent execution of a set of Serializable transactions is guaranteed to produce the same effect as running them one at a time in some order. The other three levels are defined in terms of phenomena, resulting from interaction between concurrent transactions, which must not occur at each level. The standard notes that due to the definition of Serializable, none of these phenomena are possible at that level. (This is hardly surprising -- if the effect of the transactions must be consistent with having been run one at a time, how could you see any phenomena caused by interactions?)

The phenomena which are prohibited at various levels are:

dirty read
A transaction reads data written by a concurrent uncommitted transaction.

nonrepetable read
A transaction re-reads data it has previously read and finds that data has been modified by another transaction (that committed since the initial read).

phantom read
A transaction re-executes a query returning a set of rows that satisfy a search condition and finds that the set of rows satisfying the condition has changed due to another recently-committed transaction.

serialization anomaly
The result of successfully committing a group of transactions is inconsistent with all possible orderings of running those transactions one at a time.
The SQL standard and Postgres Pro-implemented transaction isolation levels are described in Table 13.1.

### Table 13.1. Transaction Isolation Levels

</tr>
</tbody>
</table>

In Postgres Pro, you can request any of the four standard transaction isolation levels, but internally only three distinct isolation levels are implemented, i.e., Postgres Pro's Read Uncommitted mode behaves like Read Committed. This is because it is the only sensible way to map the standard isolation levels to Postgres Pro's multiversion concurrency control architecture.

The table also shows that Postgres Pro's Repeatable Read implementation does not allow phantom reads. Stricter behavior is permitted by the SQL standard: the four isolation levels only define which phenomena must not happen, not which phenomena must happen. The behavior of the available isolation levels is detailed in the following subsections.

To set the transaction isolation level of a transaction, use the command `SET TRANSACTION`.

---

**Important**

Some Postgres Pro data types and functions have special rules regarding transactional behavior. In particular, changes made to a sequence (and therefore the counter of a column declared using `serial`) are immediately visible to all other transactions and are not rolled back if the transaction that made the changes aborts. See Section 9.17 and Section 8.1.4.

---

### 13.2.1. Read Committed Isolation Level

Read Committed is the default isolation level in Postgres Pro. When a transaction uses this isolation level, a `SELECT` query (without a `FOR UPDATE/SHARE` clause) sees only data committed before the query began; it never sees either uncommitted data or changes committed during query execution by concurrent transactions. In effect, a `SELECT` query sees a snapshot of the database as of the instant the query begins to run. However, `SELECT` does see the effects of previous updates executed within its own transaction, even though they are not yet committed. Also note that two successive `SELECT` commands can see different data, even though they are within a single transaction, if other transactions commit changes after the first `SELECT` starts and before the second `SELECT` starts.

`UPDATE`, `DELETE`, `SELECT FOR UPDATE`, and `SELECT FOR SHARE` commands behave the same as `SELECT` in terms of searching for target rows: they will only find target rows that were committed as of the command start time. However, such a target row might have already been updated (or deleted or locked) by another concurrent transaction by the time it is found. In this case, the would-be updater will wait for the first updating transaction to commit or roll back (if it is still in progress). If the first updater rolls back, then its effects are negated and the second updater can proceed with updating the originally found row. If the first updater commits, the second updater will ignore the row if the first updater deleted it, otherwise it will attempt to apply its operation to the updated version of the row. The search condition of the command (the `WHERE` clause) is re-evaluated to see if the updated version of the row still matches the search condition. If so, the second updater proceeds with its operation using the updated version of the row. In the case of `SELECT FOR UPDATE` and `SELECT FOR SHARE`, this means it is the updated version of the row that is locked and returned to the client.
Concurrency Control

**INSERT** with an **ON CONFLICT DO UPDATE** clause behaves similarly. In Read Committed mode, each row proposed for insertion will either insert or update. Unless there are unrelated errors, one of those two outcomes is guaranteed. If a conflict originates in another transaction whose effects are not yet visible to the **INSERT**, the **UPDATE** clause will affect that row, even though possibly no version of that row is conventionally visible to the command.

**INSERT** with an **ON CONFLICT DO NOTHING** clause may have insertion not proceed for a row due to the outcome of another transaction whose effects are not visible to the **INSERT** snapshot. Again, this is only the case in Read Committed mode.

Because of the above rules, it is possible for an updating command to see an inconsistent snapshot: it can see the effects of concurrent updating commands on the same rows it is trying to update, but it does not see effects of those commands on other rows in the database. This behavior makes Read Committed mode unsuitable for commands that involve complex search conditions; however, it is just right for simpler cases. For example, consider updating bank balances with transactions like:

```
BEGIN;
UPDATE accounts SET balance = balance + 100.00 WHERE acctnum = 12345;
UPDATE accounts SET balance = balance - 100.00 WHERE acctnum = 7534;
COMMIT;
```

If two such transactions concurrently try to change the balance of account 12345, we clearly want the second transaction to start with the updated version of the account's row. Because each command is affecting only a predetermined row, letting it see the updated version of the row does not create any troublesome inconsistency.

More complex usage can produce undesirable results in Read Committed mode. For example, consider a **DELETE** command operating on data that is being both added and removed from its restriction criteria by another command, e.g., assume **website** is a two-row table with website.hits equaling 9 and 10:

```
BEGIN;
UPDATE website SET hits = hits + 1;
-- run from another session:  DELETE FROM website WHERE hits = 10;
COMMIT;
```

The **DELETE** will have no effect even though there is a **website.hits = 10** row before and after the **UPDATE**. This occurs because the pre-update row value 9 is skipped, and when the **UPDATE** completes and **DELETE** obtains a lock, the new row value is no longer 10 but 11, which no longer matches the criteria.

Because Read Committed mode starts each command with a new snapshot that includes all transactions committed up to that instant, subsequent commands in the same transaction will see the effects of the committed concurrent transaction in any case. The point at issue above is whether or not a single command sees an absolutely consistent view of the database.

The partial transaction isolation provided by Read Committed mode is adequate for many applications, and this mode is fast and simple to use; however, it is not sufficient for all cases. Applications that do complex queries and updates might require a more rigorously consistent view of the database than Read Committed mode provides.

### 13.2.2. Repeatable Read Isolation Level

The **Repeatable Read** isolation level only sees data committed before the transaction began; it never sees either uncommitted data or changes committed during transaction execution by concurrent transactions. (However, the query does see the effects of previous updates executed within its own transaction, even though they are not yet committed.) This is a stronger guarantee than is required by the SQL standard for this isolation level, and prevents all of the phenomena described in Table 13.1 except for serialization anomalies. As mentioned above, this is specifically allowed by the standard, which only describes the minimum protections each isolation level must provide.

This level is different from Read Committed in that a query in a repeatable read transaction sees a snapshot as of the start of the first non-transaction-control statement in the transaction, not as of the
Concurrency Control

start of the current statement within the transaction. Thus, successive **SELECT** commands within a *single* transaction see the same data, i.e., they do not see changes made by other transactions that committed after their own transaction started.

Applications using this level must be prepared to retry transactions due to serialization failures.

**UPDATE, DELETE, SELECT FOR UPDATE, and SELECT FOR SHARE** commands behave the same as **SELECT** in terms of searching for target rows: they will only find target rows that were committed as of the transaction start time. However, such a target row might have already been updated (or deleted or locked) by another concurrent transaction by the time it is found. In this case, the repeatable read transaction will wait for the first updating transaction to commit or roll back (if it is still in progress). If the first updater rolls back, then its effects are negated and the repeatable read transaction can proceed with updating the originally found row. But if the first updater commits (and actually updated or deleted the row, not just locked it) then the repeatable read transaction will be rolled back with the message

**ERROR: could not serialize access due to concurrent update**

because a repeatable read transaction cannot modify or lock rows changed by other transactions after the repeatable read transaction began.

When an application receives this error message, it should abort the current transaction and retry the whole transaction from the beginning. The second time through, the transaction will see the previously-committed change as part of its initial view of the database, so there is no logical conflict in using the new version of the row as the starting point for the new transaction's update.

Note that only updating transactions might need to be retried; read-only transactions will never have serialization conflicts.

The Repeatable Read mode provides a rigorous guarantee that each transaction sees a completely stable view of the database. However, this view will not necessarily always be consistent with some serial (one at a time) execution of concurrent transactions of the same level. For example, even a read-only transaction at this level may see a control record updated to show that a batch has been completed but *not* see one of the detail records which is logically part of the batch because it read an earlier revision of the control record. Attempts to enforce business rules by transactions running at this isolation level are not likely to work correctly without careful use of explicit locks to block conflicting transactions.

The Repeatable Read isolation level is implemented using a technique known in academic database literature and in some other database products as **Snapshot Isolation**. Differences in behavior and performance may be observed when compared with systems that use a traditional locking technique that reduces concurrency. Some other systems may even offer Repeatable Read and Snapshot Isolation as distinct isolation levels with different behavior. The permitted phenomena that distinguish the two techniques were not formalized by database researchers until after the SQL standard was developed, and are outside the scope of this manual. For a full treatment, please see [berenson95](#).

**Note**

Prior to PostgreSQL version 9.1, a request for the Serializable transaction isolation level provided exactly the same behavior described here. To retain the legacy Serializable behavior, Repeatable Read should now be requested.

### 13.2.3. Serializable Isolation Level

The **Serializable** isolation level provides the strictest transaction isolation. This level emulates serial transaction execution for all committed transactions; as if transactions had been executed one after another, serially, rather than concurrently. However, like the Repeatable Read level, applications using this level must be prepared to retry transactions due to serialization failures. In fact, this isolation level works exactly the same as Repeatable Read except that it monitors for conditions which could make execution of a concurrent set of serializable transactions behave in a manner inconsistent with
all possible serial (one at a time) executions of those transactions. This monitoring does not introduce any blocking beyond that present in repeatable read, but there is some overhead to the monitoring, and detection of the conditions which could cause a serialization anomaly will trigger a serialization failure.

As an example, consider a table `mytab`, initially containing:

<table>
<thead>
<tr>
<th>class</th>
<th>value</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>10</td>
</tr>
<tr>
<td>1</td>
<td>20</td>
</tr>
<tr>
<td>2</td>
<td>100</td>
</tr>
<tr>
<td>2</td>
<td>200</td>
</tr>
</tbody>
</table>

Suppose that serializable transaction A computes:

```sql
SELECT SUM(value) FROM mytab WHERE class = 1;
```

and then inserts the result (30) as the value in a new row with `class = 2`. Concurrently, serializable transaction B computes:

```sql
SELECT SUM(value) FROM mytab WHERE class = 2;
```

and obtains the result 300, which it inserts in a new row with `class = 1`. Then both transactions try to commit. If either transaction were running at the Repeatable Read isolation level, both would be allowed to commit; but since there is no serial order of execution consistent with the result, using Serializable transactions will allow one transaction to commit and will roll the other back with this message:

```
ERROR:  could not serialize access due to read/write dependencies among transactions
```

This is because if A had executed before B, B would have computed the sum 330, not 300, and similarly the other order would have resulted in a different sum computed by A.

When relying on Serializable transactions to prevent anomalies, it is important that any data read from a permanent user table not be considered valid until the transaction which read it has successfully committed. This is true even for read-only transactions, except that data read within a deferrable read-only transaction is known to be valid as soon as it is read, because such a transaction waits until it can acquire a snapshot guaranteed to be free from such problems before starting to read any data. In all other cases applications must not depend on results read during a transaction that later aborted; instead, they should retry the transaction until it succeeds.

To guarantee true serializability Postgres Pro uses predicate locking, which means that it keeps locks which allow it to determine when a write would have had an impact on the result of a previous read from a concurrent transaction, had it run first. In Postgres Pro these locks do not cause any blocking and therefore can not play any part in causing a deadlock. They are used to identify and flag dependencies among concurrent Serializable transactions which in certain combinations can lead to serialization anomalies. In contrast, a Read Committed or Repeatable Read transaction which wants to ensure data consistency may need to take out a lock on an entire table, which could block other users attempting to use that table, or it may use `SELECT FOR UPDATE` or `SELECT FOR SHARE` which not only can block other transactions but cause disk access.

Predicate locks in Postgres Pro, like in most other database systems, are based on data actually accessed by a transaction. These will show up in the `pg_locks` system view with a mode of `SIReadLock`. The particular locks acquired during execution of a query will depend on the plan used by the query, and multiple finer-grained locks (e.g., tuple locks) may be combined into fewer coarser-grained locks (e.g., page locks) during the course of the transaction to prevent exhaustion of the memory used to track the locks. A `READ ONLY` transaction may be able to release its SIRead locks before completion, if it detects that no conflicts can still occur which could lead to a serialization anomaly. In fact, `READ ONLY` transactions will often be able to establish that fact at startup and avoid taking any predicate locks. If you explicitly request a `SERIALIZABLE READ ONLY DEFERRABLE` transaction, it will block until it can establish this fact. (This is the only case where Serializable transactions block but Repeatable Read transactions don’t.) On the other hand, SIRead locks often need to be kept past transaction commit, until overlapping read write transactions complete.
Consistent use of Serializable transactions can simplify development. The guarantee that any set of successfully committed concurrent Serializable transactions will have the same effect as if they were run one at a time means that if you can demonstrate that a single transaction, as written, will do the right thing when run by itself, you can have confidence that it will do the right thing in any mix of Serializable transactions, even without any information about what those other transactions might do, or it will not successfully commit. It is important that an environment which uses this technique have a generalized way of handling serialization failures (which always return with an SQLSTATE value of '40001'), because it will be very hard to predict exactly which transactions might contribute to the read/write dependencies and need to be rolled back to prevent serialization anomalies. The monitoring of read/write dependencies has a cost, as does the restart of transactions which are terminated with a serialization failure, but balanced against the cost and blocking involved in use of explicit locks and SELECT FOR UPDATE or SELECT FOR SHARE, Serializable transactions are the best performance choice for some environments.

While Postgres Pro's Serializable transaction isolation level only allows concurrent transactions to commit if it can prove there is a serial order of execution that would produce the same effect, it doesn't always prevent errors from being raised that would not occur in true serial execution. In particular, it is possible to see unique constraint violations caused by conflicts with overlapping Serializable transactions even after explicitly checking that the key isn't present before attempting to insert it. This can be avoided by making sure that all Serializable transactions that insert potentially conflicting keys explicitly check if they can do so first. For example, imagine an application that asks the user for a new key and then checks that it doesn't exist already by trying to select it first, or generates a new key by selecting the maximum existing key and adding one. If some Serializable transactions insert new keys directly without following this protocol, unique constraints violations might be reported even in cases where they could not occur in a serial execution of the concurrent transactions.

For optimal performance when relying on Serializable transactions for concurrency control, these issues should be considered:

- Declare transactions as READ ONLY when possible.
- Control the number of active connections, using a connection pool if needed. This is always an important performance consideration, but it can be particularly important in a busy system using Serializable transactions.
- Don't put more into a single transaction than needed for integrity purposes.
- Don't leave connections dangling “idle in transaction” longer than necessary. The configuration parameter idle_in_transaction_session_timeout may be used to automatically disconnect lingering sessions.
- Eliminate explicit locks, SELECT FOR UPDATE, and SELECT FOR SHARE where no longer needed due to the protections automatically provided by Serializable transactions.
- When the system is forced to combine multiple page-level predicate locks into a single relation-level predicate lock because the predicate lock table is short of memory, an increase in the rate of serialization failures may occur. You can avoid this by increasing max_pred_locks_per_transaction, max_pred_locks_per_relation, and/or max_pred_locks_per_page.
- A sequential scan will always necessitate a relation-level predicate lock. This can result in an increased rate of serialization failures. It may be helpful to encourage the use of index scans by reducing random_page_cost and/or increasing cpu_tuple_cost. Be sure to weigh any decrease in transaction rollbacks and restarts against any overall change in query execution time.

The Serializable isolation level is implemented using a technique known in academic database literature as Serializable Snapshot Isolation, which builds on Snapshot Isolation by adding checks for serialization anomalies. Some differences in behavior and performance may be observed when compared with other systems that use a traditional locking technique. Please see ports12 for detailed information.

### 13.3. Explicit Locking

Postgres Pro provides various lock modes to control concurrent access to data in tables. These modes can be used for application-controlled locking in situations where MVCC does not give the desired behavior.
Also, most Postgres Pro commands automatically acquire locks of appropriate modes to ensure that referenced tables are not dropped or modified in incompatible ways while the command executes. (For example, `TRUNCATE` cannot safely be executed concurrently with other operations on the same table, so it obtains an `ACCESS EXCLUSIVE` lock on the table to enforce that.)

To examine a list of the currently outstanding locks in a database server, use the `pg_locks` system view. For more information on monitoring the status of the lock manager subsystem, refer to Chapter 26.

### 13.3.1. Table-Level Locks

The list below shows the available lock modes and the contexts in which they are used automatically by Postgres Pro. You can also acquire any of these locks explicitly with the command `LOCK`. Remember that all of these lock modes are table-level locks, even if the name contains the word “row”; the names of the lock modes are historical. To some extent the names reflect the typical usage of each lock mode — but the semantics are all the same. The only real difference between one lock mode and another is the set of lock modes with which each conflicts (see Table 13.2). Two transactions cannot hold locks of conflicting modes on the same table at the same time. (However, a transaction never conflicts with itself. For example, it might acquire `ACCESS EXCLUSIVE` lock and later acquire `ACCESS SHARE` lock on the same table.) Non-conflicting lock modes can be held concurrently by many transactions. Notice in particular that some lock modes are self-conflicting (for example, an `ACCESS EXCLUSIVE` lock cannot be held by more than one transaction at a time) while others are not self-conflicting (for example, an `ACCESS SHARE` lock can be held by multiple transactions).

#### Table-Level Lock Modes

**ACCESS SHARE**

- **Conflicts with the `ACCESS EXCLUSIVE` lock mode only.**

  The `SELECT` command acquires a lock of this mode on referenced tables. In general, any query that only *reads* a table and does not modify it will acquire this lock mode.

**ROW SHARE**

- **Conflicts with the `EXCLUSIVE` and `ACCESS EXCLUSIVE` lock modes.**

  The `SELECT FOR UPDATE` and `SELECT FOR SHARE` commands acquire a lock of this mode on the target table(s) (in addition to `ACCESS SHARE` locks on any other tables that are referenced but not selected FOR UPDATE/FOR SHARE).

**ROW EXCLUSIVE**

- **Conflicts with the `SHARE`, `SHARE ROW EXCLUSIVE`, `EXCLUSIVE`, and `ACCESS EXCLUSIVE` lock modes.**

  The commands `UPDATE`, `DELETE`, and `INSERT` acquire this lock mode on the target table (in addition to `ACCESS SHARE` locks on any other referenced tables). In general, this lock mode will be acquired by any command that *modifies data* in a table.

**SHARE UPDATE EXCLUSIVE**

- **Conflicts with the `SHARE UPDATE EXCLUSIVE`, `SHARE`, `SHARE ROW EXCLUSIVE`, `EXCLUSIVE`, and `ACCESS EXCLUSIVE` lock modes.** This mode protects a table against concurrent schema changes and VACUUM runs.

  Acquired by VACUUM (without FULL), ANALYZE, CREATE INDEX CONCURRENTLY, REINDEX CONCURRENTLY, CREATE STATISTICS, and certain `ALTER INDEX` and `ALTER TABLE` variants (for full details see the documentation of these commands).

**SHARE**

- **Conflicts with the `ROW EXCLUSIVE`, `SHARE UPDATE EXCLUSIVE`, `SHARE ROW EXCLUSIVE`, `EXCLUSIVE`, and `ACCESS EXCLUSIVE` lock modes.** This mode protects a table against concurrent data changes.
Concurrent Control

Acquired by CREATE INDEX (without CONCURRENTLY).

SHARE ROW EXCLUSIVE

Conflicts with the ROW EXCLUSIVE, SHARE UPDATE EXCLUSIVE, SHARE, SHARE ROW Exclusive, EXCLUSIVE, and ACCESS EXCLUSIVE lock modes. This mode protects a table against concurrent data changes, and is self-exclusive so that only one session can hold it at a time.

Acquired by CREATE TRIGGER and some forms of ALTER TABLE.

EXCLUSIVE

Conflicts with the ROW SHARE, ROW EXCLUSIVE, SHARE UPDATE EXCLUSIVE, SHARE, SHARE ROW Exclusive, EXCLUSIVE, and ACCESS EXCLUSIVE lock modes. This mode allows only concurrent ACCESS SHARE locks, i.e., only reads from the table can proceed in parallel with a transaction holding this lock mode.

Acquired by REFRESH MATERIALIZED VIEW CONCURRENTLY.

ACCESS EXCLUSIVE

Conflicts with locks of ACCESS SHARE, ROW SHARE, ROW EXCLUSIVE, SHARE UPDATE EXCLUSIVE, SHARE, SHARE ROW Exclusive, EXCLUSIVE, and ACCESS EXCLUSIVE mode. This mode guarantees that the holder is the only transaction accessing the table in any way.

Acquired by the DROP TABLE, TRUNCATE, REINDEX, CLUSTER, VACUUM FULL, and REFRESH MATERIALIZED VIEW (without CONCURRENTLY) commands. Many forms of ALTER INDEX and ALTER TABLE also acquire a lock at this level. This is also the default lock mode for LOCK TABLE statements that do not specify a mode explicitly.

Tip

Only an ACCESS EXCLUSIVE lock blocks a SELECT (without FOR UPDATE/SHARE) statement.

Besides, there are two additional lock modes designed to support 1C Enterprise. These modes do not conflict with any other lock modes described above. Their use is possible, but not encouraged, as advisory locks provide the same functionality.

APPLICATION SHARE

Conflicts with the APPLICATION EXCLUSIVE lock mode only.

APPLICATION EXCLUSIVE

Conflicts with the APPLICATION SHARE and APPLICATION EXCLUSIVE lock modes.

Once acquired, a lock is normally held until the end of the transaction. But if a lock is acquired after establishing a savepoint, the lock is released immediately if the savepoint is rolled back to. This is consistent with the principle that ROLLBACK cancels all effects of the commands since the savepoint. The same holds for locks acquired within a PL/pgSQL exception block: an error escape from the block releases locks acquired within it.

### 13.3.2. Row-Level Locks

In addition to table-level locks, there are row-level locks, which are listed as below with the contexts in which they are used automatically by Postgres Pro. See Table 13.3 for a complete table of row-level lock conflicts. Note that a transaction can hold conflicting locks on the same row, even in different subtransactions; but other than that, two transactions can never hold conflicting locks on the same row. Row-level locks do not affect data querying; they block only writers and lockers to the same row. Row-level locks are released at transaction end or during savepoint rollback, just like table-level locks.

#### Row-Level Lock Modes

**FOR UPDATE**

For update causes the rows retrieved by the SELECT statement to be locked as though for update. This prevents them from being locked, modified or deleted by other transactions until the current transaction ends. That is, other transactions that attempt UPDATE, DELETE, SELECT FOR UPDATE, SELECT FOR NO KEY UPDATE, SELECT FOR SHARE or SELECT FOR KEY SHARE of these rows will be blocked until the current transaction ends; conversely, SELECT FOR UPDATE will wait for a concurrent transaction that has run any of those commands on the same row, and will then lock and return the updated row (or no row, if the row was deleted). Within a REPEATABLE READ or SERIALIZABLE transaction, however, an error will be thrown if a row to be locked has changed since the transaction started. For further discussion see Section 13.4.

The FOR UPDATE lock mode is also acquired by any DELETE on a row, and also by an UPDATE that modifies the values of certain columns. Currently, the set of columns considered for the UPDATE case are those that have a unique index on them that can be used in a foreign key (so partial indexes and expressional indexes are not considered), but this may change in the future.

**FOR NO KEY UPDATE**

Behaves similarly to FOR UPDATE, except that the lock acquired is weaker: this lock will not block SELECT FOR KEY SHARE commands that attempt to acquire a lock on the same rows. This lock mode is also acquired by any UPDATE that does not acquire a FOR UPDATE lock.
CONCURRENCY CONTROL

FOR SHARE

Behaves similarly to FOR NO KEY UPDATE, except that it acquires a shared lock rather than exclusive lock on each retrieved row. A shared lock blocks other transactions from performing UPDATE, DELETE, SELECT FOR UPDATE or SELECT FOR NO KEY UPDATE on these rows, but it does not prevent them from performing SELECT FOR SHARE or SELECT FOR KEY SHARE.

FOR KEY SHARE

Behaves similarly to FOR SHARE, except that the lock is weaker: SELECT FOR UPDATE is blocked, but not SELECT FOR NO KEY UPDATE. A key-shared lock blocks other transactions from performing DELETE or any UPDATE that changes the key values, but not other UPDATE, and neither does it prevent SELECT FOR NO KEY UPDATE, SELECT FOR SHARE, or SELECT FOR KEY SHARE.

Postgres Pro doesn’t remember any information about modified rows in memory, so there is no limit on the number of rows locked at one time. However, locking a row might cause a disk write, e.g., SELECT FOR UPDATE modifies selected rows to mark them locked, and so will result in disk writes.

Table 13.3. Conflicting Row-Level Locks

<table>
<thead>
<tr>

</tr>
<tr>
<td>FOR SHARE</td>
<td></td>
</tr>
<tr>
<td>FOR NO KEY UPDATE</td>
<td></td>
</tr>
<tr>
<td>FOR UPDATE</td>
<td>X</td>
</tr>
</tbody>
</table>

13.3.3. Page-Level Locks

In addition to table and row locks, page-level share/exclusive locks are used to control read/write access to table pages in the shared buffer pool. These locks are released immediately after a row is fetched or updated. Application developers normally need not be concerned with page-level locks, but they are mentioned here for completeness.

13.3.4. Deadlocks

The use of explicit locking can increase the likelihood of deadlocks, wherein two (or more) transactions each hold locks that the other wants. For example, if transaction 1 acquires an exclusive lock on table A and then tries to acquire an exclusive lock on table B, while transaction 2 has already exclusive-locked table B and now wants an exclusive lock on table A, then neither one can proceed. Postgres Pro automatically detects deadlock situations and resolves them by aborting one of the transactions involved, allowing the other(s) to complete. (Exactly which transaction will be aborted is difficult to predict and should not be relied upon.)

Note that deadlocks can also occur as the result of row-level locks (and thus, they can occur even if explicit locking is not used). Consider the case in which two concurrent transactions modify a table. The first transaction executes:

```sql
UPDATE accounts SET balance = balance + 100.00 WHERE acctnum = 11111;
```

This acquires a row-level lock on the row with the specified account number. Then, the second transaction executes:

```sql
UPDATE accounts SET balance = balance + 100.00 WHERE acctnum = 22222;
UPDATE accounts SET balance = balance - 100.00 WHERE acctnum = 11111;
```

The first UPDATE statement successfully acquires a row-level lock on the specified row, so it succeeds in updating that row. However, the second UPDATE statement finds that the row it is attempting to update has already been locked, so it waits for the transaction that acquired the lock to complete. Transaction two is now waiting on transaction one to complete before it continues execution. Now, transaction one executes:
Concurrency Control

UPDATE accounts SET balance = balance - 100.00 WHERE acctnum = 22222;

Transaction one attempts to acquire a row-level lock on the specified row, but it cannot: transaction two already holds such a lock. So it waits for transaction two to complete. Thus, transaction one is blocked on transaction two, and transaction two is blocked on transaction one: a deadlock condition. PostgreSQL will detect this situation and abort one of the transactions.

The best defense against deadlocks is generally to avoid them by being certain that all applications using a database acquire locks on multiple objects in a consistent order. In the example above, if both transactions had updated the rows in the same order, no deadlock would have occurred. One should also ensure that the first lock acquired on an object in a transaction is the most restrictive mode that will be needed for that object. If it is not feasible to verify this in advance, then deadlocks can be handled on-the-fly by retrying transactions that abort due to deadlocks.

So long as no deadlock situation is detected, a transaction seeking either a table-level or row-level lock will wait indefinitely for conflicting locks to be released. This means it is a bad idea for applications to hold transactions open for long periods of time (e.g., while waiting for user input).

13.3.5. Advisory Locks

PostgreSQL provides a means for creating locks that have application-defined meanings. These are called advisory locks, because the system does not enforce their use — it is up to the application to use them correctly. Advisory locks can be useful for locking strategies that are an awkward fit for the MVCC model. For example, a common use of advisory locks is to emulate pessimistic locking strategies typical of so-called “flat file” data management systems. While a flag stored in a table could be used for the same purpose, advisory locks are faster, avoid table bloat, and are automatically cleaned up by the server at the end of the session.

There are two ways to acquire an advisory lock in PostgreSQL: at session level or at transaction level. Once acquired at session level, an advisory lock is held until explicitly released or the session ends. Unlike standard lock requests, session-level advisory lock requests do not honor transaction semantics: a lock acquired during a transaction that is later rolled back will still be held following the rollback, and likewise an unlock is effective even if the calling transaction fails later. A lock can be acquired multiple times by its owning process; for each completed lock request there must be a corresponding unlock request before the lock is actually released. Transaction-level lock requests, on the other hand, behave more like regular lock requests: they are automatically released at the end of the transaction, and there is no explicit unlock operation. This behavior is often more convenient than the session-level behavior for short-term usage of an advisory lock. Session-level and transaction-level lock requests for the same advisory lock identifier will block each other in the expected way. If a session already holds a given advisory lock, additional requests by it will always succeed, even if other sessions are awaiting the lock; this statement is true regardless of whether the existing lock hold and new request are at session level or transaction level.

Like all locks in PostgreSQL, a complete list of advisory locks currently held by any session can be found in the pg_locks system view.

Both advisory locks and regular locks are stored in a shared memory pool whose size is defined by the configuration variables max_locks_per_transaction and max_connections. Care must be taken not to exhaust this memory or the server will be unable to grant any locks at all. This imposes an upper limit on the number of advisory locks grantable by the server, typically in the tens to hundreds of thousands depending on how the server is configured.

In certain cases using advisory locking methods, especially in queries involving explicit ordering and LIMIT clauses, care must be taken to control the locks acquired because of the order in which SQL expressions are evaluated. For example:

SELECT pg_advisory_lock(id) FROM foo WHERE id = 12345; -- ok
SELECT pg_advisory_lock(id) FROM foo WHERE id > 12345 LIMIT 100; -- danger!
SELECT pg_advisory_lock(q.id) FROM
Concurrent Control

13.4. Data Consistency Checks at the Application Level

It is very difficult to enforce business rules regarding data integrity using Read Committed transactions because the view of the data is shifting with each statement, and even a single statement may not restrict itself to the statement's snapshot if a write conflict occurs.

While a Repeatable Read transaction has a stable view of the data throughout its execution, there is a subtle issue with using MVCC snapshots for data consistency checks, involving something known as read/write conflicts. If one transaction writes data and a concurrent transaction attempts to read the same data (whether before or after the write), it cannot see the work of the other transaction. The reader then appears to have executed first regardless of which started first or which committed first. If that is as far as it goes, there is no problem, but if the reader also writes data which is read by a concurrent transaction there is now a transaction which appears to have run before either of the previously mentioned transactions. If the transaction which appears to have executed last actually commits first, it is very easy for a cycle to appear in a graph of the order of execution of the transactions. When such a cycle appears, integrity checks will not work correctly without some help.

As mentioned in Section 13.2.3, Serializable transactions are just Repeatable Read transactions which add nonblocking monitoring for dangerous patterns of read/write conflicts. When a pattern is detected which could cause a cycle in the apparent order of execution, one of the transactions involved is rolled back to break the cycle.

13.4.1. Enforcing Consistency with Serializable Transactions

If the Serializable transaction isolation level is used for all writes and for all reads which need a consistent view of the data, no other effort is required to ensure consistency. Software from other environments which is written to use serializable transactions to ensure consistency should “just work” in this regard in Postgres Pro.

When using this technique, it will avoid creating an unnecessary burden for application programmers if the application software goes through a framework which automatically retries transactions which are rolled back with a serialization failure. It may be a good idea to set default_transaction_isolation to serializable. It would also be wise to take some action to ensure that no other transaction isolation level is used, either inadvertently or to subvert integrity checks, through checks of the transaction isolation level in triggers.

See Section 13.2.3 for performance suggestions.

Warning

This level of integrity protection using Serializable transactions does not yet extend to hot standby mode (Section 25.4). Because of that, those using hot standby may want to use Repeatable Read and explicit locking on the primary.

13.4.2. Enforcing Consistency with Explicit Blocking Locks

When non-serializable writes are possible, to ensure the current validity of a row and protect it against concurrent updates one must use SELECT FOR UPDATE, SELECT FOR SHARE, or an appropriate LOCK TABLE statement. (SELECT FOR UPDATE and SELECT FOR SHARE lock just the returned rows against concurrent
updates, while \texttt{LOCK TABLE} locks the whole table.) This should be taken into account when porting applications to Postgres Pro from other environments.

Also of note to those converting from other environments is the fact that \texttt{SELECT FOR UPDATE} does not ensure that a concurrent transaction will not update or delete a selected row. To do that in Postgres Pro you must actually update the row, even if no values need to be changed. \texttt{SELECT FOR UPDATE} temporarily blocks other transactions from acquiring the same lock or executing an \texttt{UPDATE} or \texttt{DELETE} which would affect the locked row, but once the transaction holding this lock commits or rolls back, a blocked transaction will proceed with the conflicting operation unless an actual \texttt{UPDATE} of the row was performed while the lock was held.

Global validity checks require extra thought under non-serializable MVCC. For example, a banking application might wish to check that the sum of all credits in one table equals the sum of debits in another table, when both tables are being actively updated. Comparing the results of two successive \texttt{SELECT \text{sum}(...)\texttt{commands will not work reliably in Read Committed mode, since the second query will likely include the results of transactions not counted by the first. Doing the two sums in a single repeatable read transaction will give an accurate picture of only the effects of transactions that committed before the repeatable read transaction started — but one might legitimately wonder whether the answer is still relevant by the time it is delivered. If the repeatable read transaction itself applied some changes before trying to make the consistency check, the usefulness of the check becomes even more debatable, since now it includes some but not all post-transaction-start changes. In such cases a careful person might wish to lock all tables needed for the check, in order to get an indisputable picture of current reality. A \texttt{SHARE} mode (or higher) lock guarantees that there are no uncommitted changes in the locked table, other than those of the current transaction.

Note also that if one is relying on explicit locking to prevent concurrent changes, one should either use Read Committed mode, or in Repeatable Read mode be careful to obtain locks before performing queries. A lock obtained by a repeatable read transaction guarantees that no other transactions modifying the table are still running, but if the snapshot seen by the transaction predates obtaining the lock, it might predate some now-committed changes in the table. A repeatable read transaction's snapshot is actually frozen at the start of its first query or data-modification command (\texttt{SELECT}, \texttt{INSERT}, \texttt{UPDATE}, or \texttt{DELETE}), so it is possible to obtain locks explicitly before the snapshot is frozen.

### 13.5. Caveats

Some DDL commands, currently only \texttt{TRUNCATE} and the table-rewriting forms of \texttt{ALTER TABLE}, are not MVCC-safe. This means that after the truncation or rewrite commits, the table will appear empty to concurrent transactions, if they are using a snapshot taken before the DDL command committed. This will only be an issue for a transaction that did not access the table in question before the DDL command started — any transaction that has done so would hold at least an \texttt{ACCESS SHARE} table lock, which would block the DDL command until that transaction completes. So these commands will not cause any apparent inconsistency in the table contents for successive queries on the target table, but they could cause visible inconsistency between the contents of the target table and other tables in the database.

Support for the Serializable transaction isolation level has not yet been added to Hot Standby replication targets (described in Section 25.4). The strictest isolation level currently supported in hot standby mode is Repeatable Read. While performing all permanent database writes within Serializable transactions on the primary will ensure that all standbys will eventually reach a consistent state, a Repeatable Read transaction run on the standby can sometimes see a transient state that is inconsistent with any serial execution of the transactions on the primary.

Internal access to the system catalogs is not done using the isolation level of the current transaction. This means that newly created database objects such as tables are visible to concurrent Repeatable Read and Serializable transactions, even though the rows they contain are not. In contrast, queries that explicitly examine the system catalogs don't see rows representing concurrently created database objects, in the higher isolation levels.

### 13.6. Locking and Indexes
Though Postgres Pro provides nonblocking read/write access to table data, nonblocking read/write access is not currently offered for every index access method implemented in Postgres Pro. The various index types are handled as follows:

**B-tree, GiST and SP-GiST indexes**

Short-term share/exclusive page-level locks are used for read/write access. Locks are released immediately after each index row is fetched or inserted. These index types provide the highest concurrency without deadlock conditions.

**Hash indexes**

Share/exclusive hash-bucket-level locks are used for read/write access. Locks are released after the whole bucket is processed. Bucket-level locks provide better concurrency than index-level ones, but deadlock is possible since the locks are held longer than one index operation.

**GIN indexes**

Short-term share/exclusive page-level locks are used for read/write access. Locks are released immediately after each index row is fetched or inserted. But note that insertion of a GIN-indexed value usually produces several index key insertions per row, so GIN might do substantial work for a single value’s insertion.

Currently, B-tree indexes offer the best performance for concurrent applications; since they also have more features than hash indexes, they are the recommended index type for concurrent applications that need to index scalar data. When dealing with non-scalar data, B-trees are not useful, and GiST, SP-GiST or GIN indexes should be used instead.
Chapter 14. Performance Tips

Query performance can be affected by many things. Some of these can be controlled by the user, while others are fundamental to the underlying design of the system. This chapter provides some hints about understanding and tuning Postgres Pro performance.

14.1. Using EXPLAIN

Postgres Pro devises a query plan for each query it receives. Choosing the right plan to match the query structure and the properties of the data is absolutely critical for good performance, so the system includes a complex planner that tries to choose good plans. You can use the EXPLAIN command to see what query plan the planner creates for any query. Plan-reading is an art that requires some experience to master, but this section attempts to cover the basics.

Examples in this section are drawn from the regression test database after doing a VACUUM ANALYZE, using 9.3 development sources. You should be able to get similar results if you try the examples yourself, but your estimated costs and row counts might vary slightly because ANALYZE’s statistics are random samples rather than exact, and because costs are inherently somewhat platform-dependent.

The examples use EXPLAIN’s default “text” output format, which is compact and convenient for humans to read. If you want to feed EXPLAIN’s output to a program for further analysis, you should use one of its machine-readable output formats (XML, JSON, or YAML) instead.

14.1.1. EXPLAIN Basics

The structure of a query plan is a tree of plan nodes. Nodes at the bottom level of the tree are scan nodes: they return raw rows from a table. There are different types of scan nodes for different table access methods: sequential scans, index scans, and bitmap index scans. There are also non-table row sources, such as VALUES clauses and set-returning functions in FROM, which have their own scan node types. If the query requires joining, aggregation, sorting, or other operations on the raw rows, then there will be additional nodes above the scan nodes to perform these operations. Again, there is usually more than one possible way to do these operations, so different node types can appear here too. The output of EXPLAIN has one line for each node in the plan tree, showing the basic node type plus the cost estimates that the planner made for the execution of that plan node. Additional lines might appear, indented from the node’s summary line, to show additional properties of the node. The very first line (the summary line for the topmost node) has the estimated total execution cost for the plan; it is this number that the planner seeks to minimize.

Here is a trivial example, just to show what the output looks like:

EXPLAIN SELECT * FROM tenk1;

QUERY PLAN
-------------------------------------------------------------
Seq Scan on tenk1  (cost=0.00..458.00 rows=10000 width=244)

Since this query has no WHERE clause, it must scan all the rows of the table, so the planner has chosen to use a simple sequential scan plan. The numbers that are quoted in parentheses are (left to right):

• Estimated start-up cost. This is the time expended before the output phase can begin, e.g., time to do the sorting in a sort node.

• Estimated total cost. This is stated on the assumption that the plan node is run to completion, i.e., all available rows are retrieved. In practice a node’s parent node might stop short of reading all available rows (see the LIMIT example below).

• Estimated number of rows output by this plan node. Again, the node is assumed to be run to completion.

• Estimated average width of rows output by this plan node (in bytes).
The costs are measured in arbitrary units determined by the planner's cost parameters (see Section 18.7.2). Traditional practice is to measure the costs in units of disk page fetches; that is, \texttt{seq\_page\_cost} is conventionally set to 1.0 and the other cost parameters are set relative to that. The examples in this section are run with the default cost parameters.

It’s important to understand that the cost of an upper-level node includes the cost of all its child nodes. It’s also important to realize that the cost only reflects things that the planner cares about. In particular, the cost does not consider the time spent transmitting result rows to the client, which could be an important factor in the real elapsed time; but the planner ignores it because it cannot change it by altering the plan. (Every correct plan will output the same row set, we trust.)

The \texttt{rows} value is a little tricky because it is not the number of rows processed or scanned by the plan node, but rather the number emitted by the node. This is often less than the number scanned, as a result of filtering by any \texttt{WHERE}-clause conditions that are being applied at the node. Ideally the top-level rows estimate will approximate the number of rows actually returned, updated, or deleted by the query.

Returning to our example:

\begin{verbatim}
EXPLAIN SELECT * FROM tenk1;

QUERY PLAN
-------------------------------------------------------------
Seq Scan on tenk1  (cost=0.00..458.00 rows=10000 width=244)

These numbers are derived very straightforwardly. If you do:

```sql
SELECT relpages, reltuples FROM pg_class WHERE relname = 'tenk1';
```

you will find that \texttt{tenk1} has 358 disk pages and 10000 rows. The estimated cost is computed as \(\text{disk pages read} \times \text{seq\_page\_cost} + \text{rows scanned} \times \text{cpu\_tuple\_cost}\). By default, \texttt{seq\_page\_cost} is 1.0 and \texttt{cpu\_tuple\_cost} is 0.01, so the estimated cost is \((358 \times 1.0) + (10000 \times 0.01) = 458\).

Now let’s modify the query to add a \texttt{WHERE} condition:

\begin{verbatim}
EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 7000;

QUERY PLAN
------------------------------------------------------------
Seq Scan on tenk1  (cost=0.00..483.00 rows=7001 width=244)
Filter: (unique1 < 7000)

These numbers are derived very straightforwardly. If you do:

```sql
SELECT relpages, reltuples FROM pg_class WHERE relname = 'tenk1';
```

you will find that \texttt{tenk1} has 358 disk pages and 10000 rows. The estimated cost is computed as \(\text{disk pages read} \times \text{seq\_page\_cost} + \text{rows scanned} \times \text{cpu\_tuple\_cost}\). By default, \texttt{seq\_page\_cost} is 1.0 and \texttt{cpu\_tuple\_cost} is 0.01, so the estimated cost is \((358 \times 1.0) + (10000 \times 0.01) = 458\).

Now, let’s make the condition more restrictive:

\begin{verbatim}
EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 100;

QUERY PLAN
------------------------------------------------------------------------------
Bitmap Heap Scan on tenk1  (cost=5.07..229.20 rows=101 width=244)
   Recheck Cond: (unique1 < 100)
   ->  Bitmap Index Scan on tenk1_unique1  (cost=0.00..5.04 rows=101 width=0)

Notice that the \texttt{EXPLAIN} output shows the \texttt{WHERE} clause being applied as a “filter” condition attached to the Seq Scan plan node. This means that the plan node checks the condition for each row it scans, and outputs only the ones that pass the condition. The estimate of output rows has been reduced because of the \texttt{WHERE} clause. However, the scan will still have to visit all 10000 rows, so the cost hasn’t decreased; in fact it has gone up a bit (by 10000 \times \text{cpu\_operator\_cost}, to be exact) to reflect the extra CPU time spent checking the \texttt{WHERE} condition.

The actual number of rows this query would select is 7000, but the \texttt{rows} estimate is only approximate. If you try to duplicate this experiment, you will probably get a slightly different estimate; moreover, it can change after each \texttt{ANALYZE} command, because the statistics produced by \texttt{ANALYZE} are taken from a randomized sample of the table.

Now, let’s make the condition more restrictive:

\begin{verbatim}
EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 100;

QUERY PLAN
------------------------------------------------------------------------------
Bitmap Heap Scan on tenk1  (cost=5.07..229.20 rows=101 width=244)
   Recheck Cond: (unique1 < 100)
   ->  Bitmap Index Scan on tenk1_unique1  (cost=0.00..5.04 rows=101 width=0)

426
Here the planner has decided to use a two-step plan: the child plan node visits an index to find the locations of rows matching the index condition, and then the upper plan node actually fetches those rows from the table itself. Fetching rows separately is much more expensive than reading them sequentially, but because not all the pages of the table have to be visited, this is still cheaper than a sequential scan. (The reason for using two plan levels is that the upper plan node sorts the row locations identified by the index into physical order before reading them, to minimize the cost of separate fetches. The “bitmap” mentioned in the node names is the mechanism that does the sorting.)

Now let's add another condition to the `WHERE` clause:

```
EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 100 AND stringu1 = 'xxx';
```

```
QUERY PLAN
------------------------------------------------------------------------------
Bitmap Heap Scan on tenk1  (cost=5.04..229.43 rows=1 width=244)
  Recheck Cond: (unique1 < 100)
  Filter: (stringu1 = 'xxx'::name)
->  Bitmap Index Scan on tenk1_unique1  (cost=0.00..5.04 rows=101 width=0)
    Index Cond: (unique1 < 100)
```

The added condition `stringu1 = 'xxx'` reduces the output row count estimate, but not the cost because we still have to visit the same set of rows. Notice that the `stringu1` clause cannot be applied as an index condition, since this index is only on the `unique1` column. Instead it is applied as a filter on the rows retrieved by the index. Thus the cost has actually gone up slightly to reflect this extra checking.

In some cases the planner will prefer a “simple” index scan plan:

```
EXPLAIN SELECT * FROM tenk1 WHERE unique1 = 42;
```

```
QUERY PLAN
-----------------------------------------------------------------------------
Index Scan using tenk1_unique1 on tenk1  (cost=0.29..8.30 rows=1 width=244)
  Index Cond: (unique1 = 42)
```

In this type of plan the table rows are fetched in index order, which makes them even more expensive to read, but there are so few that the extra cost of sorting the row locations is not worth it. You'll most often see this plan type for queries that fetch just a single row. It's also often used for queries that have an `ORDER BY` condition that matches the index order, because then no extra sorting step is needed to satisfy the `ORDER BY`. In this example, adding `ORDER BY unique1` would use the same plan because the index already implicitly provides the requested ordering.

The planner may implement an `ORDER BY` clause in several ways. The above example shows that such an ordering clause may be implemented implicitly. The planner may also add an explicit `sort` step:

```
EXPLAIN SELECT * FROM tenk1 ORDER BY unique1;
```

```
QUERY PLAN
----------------------------------------------------------
Sort  (cost=1109.39..1134.39 rows=10000 width=244)
  Sort Key: unique1
->  Seq Scan on tenk1  (cost=0.00..445.00 rows=10000 width=244)
```

If a part of the plan guarantees an ordering on a prefix of the required sort keys, then the planner may instead decide to use an `incremental sort` step:

```
EXPLAIN SELECT * FROM tenk1 ORDER BY four, ten LIMIT 100;
```

```
QUERY PLAN
----------------------------------------------------------
Limit  (cost=521.06..538.05 rows=100 width=244)
->  Incremental Sort  (cost=521.06..2220.95 rows=10000 width=244)
    Sort Key: four, ten
```
Performance Tips

Presorted Key: four

->  Index Scan using index_tenk1_on_four on tenk1  (cost=0.29..1510.08 rows=10000 width=244)

Compared to regular sorts, sorting incrementally allows returning tuples before the entire result set has been sorted, which particularly enables optimizations with LIMIT queries. It may also reduce memory usage and the likelihood of spilling sorts to disk, but it comes at the cost of the increased overhead of splitting the result set into multiple sorting batches.

If there are separate indexes on several of the columns referenced in WHERE, the planner might choose to use an AND or OR combination of the indexes:

EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 100 AND unique2 > 9000;

QUERY PLAN

-------------------------------------------------------------------------------------
Bitmap Heap Scan on tenk1  (cost=25.08..60.21 rows=10 width=244)
  Recheck Cond: ((unique1 < 100) AND (unique2 > 9000))
  ->  BitmapAnd  (cost=25.08..25.08 rows=10 width=0)
  428
  ->  Bitmap Index Scan on tenk1_unique1  (cost=0.00..5.04 rows=101 width=0)
    Index Cond: (unique1 < 100)
  428
  ->  Bitmap Index Scan on tenk1_unique2  (cost=0.00..19.78 rows=999 width=0)
    Index Cond: (unique2 > 9000)

But this requires visiting both indexes, so it's not necessarily a win compared to using just one index and treating the other condition as a filter. If you vary the ranges involved you'll see the plan change accordingly.

Here is an example showing the effects of LIMIT:

EXPLAIN SELECT * FROM tenk1 WHERE unique1 < 100 AND unique2 > 9000 LIMIT 2;

QUERY PLAN

-------------------------------------------------------------------------------------
Limit  (cost=0.29..14.48 rows=2 width=244)
  ->  Index Scan using tenk1_unique2 on tenk1  (cost=0.29..71.27 rows=10 width=244)
    Index Cond: (unique2 > 9000)
  Filter: (unique1 < 100)

This is the same query as above, but we added a LIMIT so that not all the rows need be retrieved, and the planner changed its mind about what to do. Notice that the total cost and row count of the Index Scan node are shown as if it were run to completion. However, the Limit node is expected to stop after retrieving only a fifth of those rows, so its total cost is only a fifth as much, and that's the actual estimated cost of the query. This plan is preferred over adding a Limit node to the previous plan because the Limit could not avoid paying the startup cost of the bitmap scan, so the total cost would be something over 25 units with that approach.

Let's try joining two tables, using the columns we have been discussing:

EXPLAIN SELECT *
FROM tenk1 t1, tenk2 t2
WHERE t1.unique1 < 10 AND t1.unique2 = t2.unique2;

QUERY PLAN

-------------------------------------------------------------------------------------
Nested Loop  (cost=4.65..118.62 rows=10 width=488)
  ->  Bitmap Heap Scan on tenk1 t1  (cost=4.36..39.47 rows=10 width=244)
    Recheck Cond: (unique1 < 10)
      ->  Bitmap Index Scan on tenk1_unique1  (cost=0.00..4.36 rows=10 width=0)
        Index Cond: (unique1 < 10)
      ->  Index Scan using tenk2_unique2 on tenk2 t2  (cost=0.29..7.91 rows=1 width=244)
In this plan, we have a nested-loop join node with two table scans as inputs, or children. The indentation of the node summary lines reflects the plan tree structure. The join's first, or “outer”, child is a bitmap scan similar to those we saw before. Its cost and row count are the same as we'd get from

\[
\text{SELECT ... WHERE unique1 < 10}
\]

because we are applying the WHERE clause unique1 < 10 at that node. The t1.unique2 = t2.unique2 clause is not relevant yet, so it doesn’t affect the row count of the outer scan. The nested-loop join node will run its second, or “inner” child once for each row obtained from the outer child. Column values from the current outer row can be plugged into the inner scan; here, the t1.unique2 value from the outer row is available, so we get a plan and costs similar to what we saw above for a simple

\[
\text{SELECT ... WHERE t2.unique2 = constant}
\]

case. (The estimated cost is actually a bit lower than what was seen above, as a result of caching that's expected to occur during the repeated index scans on t2.) The costs of the loop node are then set on the basis of the cost of the outer scan, plus one repetition of the inner scan for each outer row (10 * 7.91, here), plus a little CPU time for join processing.

In this example the join's output row count is the same as the product of the two scans' row counts, but that's not true in all cases because there can be additional WHERE clauses that mention both tables and so can only be applied at the join point, not to either input scan. Here's an example:

```
EXPLAIN SELECT *
FROM tenk1 t1, tenk2 t2
WHERE t1.unique1 < 10 AND t2.unique2 < 10 AND t1.hundred < t2.hundred;
```

QUERY PLAN

```
Nested Loop  (cost=4.65..49.46 rows=33 width=488)
  Join Filter: (t1.hundred < t2.hundred)
    ->  Bitmap Heap Scan on tenk1 t1  (cost=4.36..39.47 rows=10 width=244)
      Recheck Cond: (unique1 < 10)
        ->  Bitmap Index Scan on tenk1_unique1  (cost=0.00..4.36 rows=10 width=0)
    ->  Materialize  (cost=0.29..8.51 rows=10 width=244)
      Index Scan using tenk2_unique2 on tenk2 t2  (cost=0.29..8.46 rows=10 width=244)
  Index Cond: (unique1 < 10)

The condition t1.hundred < t2.hundred can't be tested in the tenk2_unique2 index, so it's applied at the join node. This reduces the estimated output row count of the join node, but does not change either input scan.

Notice that here the planner has chosen to “materialize” the inner relation of the join, by putting a Materialize plan node atop it. This means that the t2 index scan will be done just once, even though the nested-loop join node needs to read that data ten times, once for each row from the outer relation. The Materialize node saves the data in memory as it's read, and then returns the data from memory on each subsequent pass.

When dealing with outer joins, you might see join plan nodes with both “Join Filter” and plain “Filter” conditions attached. Join Filter conditions come from the outer join's ON clause, so a row that fails the Join Filter condition could still get emitted as a null-extended row. But a plain Filter condition is applied after the outer-join rules and so acts to remove rows unconditionally. In an inner join there is no semantic difference between these types of filters.

If we change the query's selectivity a bit, we might get a very different join plan:

```
EXPLAIN SELECT *
FROM tenk1 t1, tenk2 t2
WHERE t1.unique1 < 100 AND t1.unique2 = t2.unique2;
```

QUERY PLAN
Here, the planner has chosen to use a hash join, in which rows of one table are entered into an in-memory hash table, after which the other table is scanned and the hash table is probed for matches to each row. Again note how the indentation reflects the plan structure: the bitmap scan on \textit{tenk1} is the input to the Hash node, which constructs the hash table. That's then returned to the Hash Join node, which reads rows from its outer child plan and searches the hash table for each one.

Another possible type of join is a merge join, illustrated here:

\begin{verbatim}
EXPLAIN SELECT * 
FROM tenk1 t1, onek t2 
WHERE t1.unique1 < 100 AND t1.unique2 = t2.unique2;
\end{verbatim}

\begin{verbatim}
SET enable_sort = off;
\end{verbatim}

One way to look at variant plans is to force the planner to disregard whatever strategy it thought was the cheapest, using the enable/disable flags described in Section 18.7.1. (This is a crude tool, but useful. See also Section 14.3.)
Performance Tips

Filter: \( (\text{unique1} < 100) \)
\[ \rightarrow \text{Index Scan using onek_unique2 on onek t2} \quad \text{(cost=0.28..224.79 rows=1000 width=244)} \]

which shows that the planner thinks that sorting \text{onek} by index-scanning is about 12% more expensive than sequential-scan-and-sort. Of course, the next question is whether it's right about that. We can investigate that using \text{EXPLAIN ANALYZE}, as discussed below.

14.1.2. \text{EXPLAIN ANALYZE}

It is possible to check the accuracy of the planner's estimates by using \text{EXPLAIN}'s \text{ANALYZE} option. With this option, \text{EXPLAIN} actually executes the query, and then displays the true row counts and true run time accumulated within each plan node, along with the same estimates that a plain \text{EXPLAIN} shows. For example, we might get a result like this:

\text{EXPLAIN ANALYZE SELECT *}
\text{FROM tenk1 t1, tenk2 t2 WHERE t1.unique1 < 10 AND t1.unique2 = t2.unique2;}

\text{QUERY PLAN}

---

\text{Nested Loop} \quad \text{(cost=4.65..118.62 rows=10 width=488) (actual time=0.128..0.377 rows=10 loops=1)}
\[ \rightarrow \text{Bitmap Heap Scan on tenk1 t1} \quad \text{(cost=4.36..39.47 rows=10 width=244) (actual time=0.057..0.121 rows=10 loops=1)} \]
\hspace{1em} \text{Recheck Cond: (unique1 < 10)}
\[ \rightarrow \text{Bitmap Index Scan on tenk1_unique1} \quad \text{(cost=0.00..4.36 rows=10 width=0) (actual time=0.024..0.024 rows=10 loops=1)} \]
\hspace{1em} \text{Index Cond: (unique1 < 10)}
\[ \rightarrow \text{Index Scan using tenk2_unique2 on tenk2 t2} \quad \text{(cost=0.29..7.91 rows=1 width=244) (actual time=0.021..0.022 rows=1 loops=10)} \]
\hspace{1em} \text{Index Cond: (unique2 = t1.unique2)}

\text{Planning time: 0.181 ms}
\text{Execution time: 0.501 ms}

Note that the “actual time” values are in milliseconds of real time, whereas the \text{cost} estimates are expressed in arbitrary units; so they are unlikely to match up. The thing that's usually most important to look for is whether the estimated row counts are reasonably close to reality. In this example the estimates were all dead-on, but that's quite unusual in practice.

In some query plans, it is possible for a subplan node to be executed more than once. For example, the inner index scan will be executed once per outer row in the above nested-loop plan. In such cases, the \text{loops} value reports the total number of executions of the node, and the actual time and rows values shown are averages per-execution. This is done to make the numbers comparable with the way that the cost estimates are shown. Multiply by the \text{loops} value to get the total time actually spent in the node. In the above example, we spent a total of 0.220 milliseconds executing the index scans on \text{tenk2}.

In some cases \text{EXPLAIN ANALYZE} shows additional execution statistics beyond the plan node execution times and row counts. For example, Sort and Hash nodes provide extra information:

\text{EXPLAIN ANALYZE SELECT *}
\text{FROM tenk1 t1, tenk2 t2 WHERE t1.unique1 < 100 AND t1.unique2 = t2.unique2 ORDER BY t1.fivethous;}

\text{QUERY PLAN}

---

Sort \quad \text{(cost=717.34..717.59 rows=101 width=488) (actual time=7.761..7.774 rows=100 loops=1)}
\hspace{1em} \text{Sort Key: t1.fivethous}
Performance Tips

Sort Method: quicksort  Memory: 77kB
->  Hash Join  (cost=230.47..713.98 rows=101 width=488) (actual time=0.711..7.427 rows=100 loops=1)
   Hash Cond: (t2.unique2 = t1.unique2)
   ->  Seq Scan on tenk2 t2  (cost=0.00..445.00 rows=10000 width=244) (actual time=0.007..2.583 rows=100 loops=1)
   ->  Hash  (cost=229.20..229.20 rows=101 width=244) (actual time=0.659..0.659 rows=100 loops=1)
      Buckets: 1024  Batches: 1  Memory Usage: 28kB
         ->  Bitmap Heap Scan on tenk1 t1  (cost=5.07..229.20 rows=101 width=244) (actual time=0.080..0.526 rows=100 loops=1)
            Recheck Cond: (unique1 < 100)
            ->  Bitmap Index Scan on tenk1_unique1  (cost=0.00..5.04 rows=101 width=0) (actual time=0.049..0.049 rows=100 loops=1)
               Index Cond: (unique1 < 100)
Planning time: 0.194 ms
Execution time: 8.008 ms

The Sort node shows the sort method used (in particular, whether the sort was in-memory or on-disk) and the amount of memory or disk space needed. The Hash node shows the number of hash buckets and batches as well as the peak amount of memory used for the hash table. (If the number of batches exceeds one, there will also be disk space usage involved, but that is not shown.)

Another type of extra information is the number of rows removed by a filter condition:

EXPLAIN ANALYZE SELECT * FROM tenk1 WHERE ten < 7;

QUERY PLAN

-------------------------------------------------------------------
| Seq Scan on tenk1  (cost=0.00..483.00 rows=7000 width=244) (actual time=0.016..5.107 rows=7000 loops=1) |
|   Filter: (ten < 7) |
|   Rows Removed by Filter: 3000 |
| Planning time: 0.083 ms |
| Execution time: 5.905 ms |

These counts can be particularly valuable for filter conditions applied at join nodes. The “Rows Removed” line only appears when at least one scanned row, or potential join pair in the case of a join node, is rejected by the filter condition.

A case similar to filter conditions occurs with “lossy” index scans. For example, consider this search for polygons containing a specific point:

EXPLAIN ANALYZE SELECT * FROM polygon_tbl WHERE f1 @> polygon '(0.5,2.0)';

QUERY PLAN

-------------------------------------------------------------------
| Seq Scan on polygon_tbl  (cost=0.00..1.05 rows=1 width=32) (actual time=0.044..0.044 rows=0 loops=1) |
|   Filter: (f1 @> '((0.5,2))'::polygon) |
|   Rows Removed by Filter: 4 |
| Planning time: 0.040 ms |
| Execution time: 0.083 ms |

The planner thinks (quite correctly) that this sample table is too small to bother with an index scan, so we have a plain sequential scan in which all the rows got rejected by the filter condition. But if we force an index scan to be used, we see:

SET enable_seqscan TO off;
EXPLAIN ANALYZE SELECT * FROM polygon_tbl WHERE f1 @> polygon '(0.5,2.0)';

-----

**QUERY PLAN**

Index Scan using gpolygonind on polygon_tbl  (cost=0.13..8.15 rows=1 width=32) (actual time=0.062..0.062 rows=0 loops=1)
  Index Cond: (f1 @> '((0.5,2))'::polygon)
Rows Removed by Index Recheck: 1
Planning time: 0.034 ms
Execution time: 0.144 ms

Here we can see that the index returned one candidate row, which was then rejected by a recheck of the index condition. This happens because a GiST index is “lossy” for polygon containment tests: it actually returns the rows with polygons that overlap the target, and then we have to do the exact containment test on those rows.

EXPLAIN has a **BUFFERS** option that can be used with ANALYZE to get even more run time statistics:

EXPLAIN (ANALYZE, BUFFERS) SELECT * FROM tenk1 WHERE unique1 < 100 AND unique2 > 9000;

-----

**QUERY PLAN**

Bitmap Heap Scan on tenk1  (cost=25.08..60.21 rows=10 width=244) (actual time=0.323..0.342 rows=10 loops=1)
  Recheck Cond: ((unique1 < 100) AND (unique2 > 9000))
  Buffers: shared hit=15
->  BitmapAnd  (cost=25.08..25.08 rows=10 width=0) (actual time=0.309..0.309 rows=0 loops=1)
    Buffers: shared hit=7
    ->  Bitmap Index Scan on tenk1_unique1  (cost=0.00..5.04 rows=101 width=0)
        (actual time=0.043..0.043 rows=100 loops=1)
          Index Cond: (unique1 < 100)
          Buffers: shared hit=2
    ->  Bitmap Index Scan on tenk1_unique2  (cost=0.00..19.78 rows=999 width=0)
        (actual time=0.227..0.227 rows=999 loops=1)
          Index Cond: (unique2 > 9000)
          Buffers: shared hit=5
Planning time: 0.088 ms
Execution time: 0.423 ms

The numbers provided by **BUFFERS** help to identify which parts of the query are the most I/O-intensive.

Keep in mind that because EXPLAIN ANALYZE actually runs the query, any side-effects will happen as usual, even though whatever results the query might output are discarded in favor of printing the EXPLAIN data. If you want to analyze a data-modifying query without changing your tables, you can roll the command back afterwards, for example:

BEGIN;

EXPLAIN ANALYZE UPDATE tenk1 SET hundred = hundred + 1 WHERE unique1 < 100;

-----

**QUERY PLAN**

Update on tenk1  (cost=5.08..230.08 rows=0 width=0) (actual time=3.791..3.792 rows=0 loops=1)
  ->  Bitmap Heap Scan on tenk1  (cost=5.08..230.08 rows=102 width=10) (actual time=0.069..0.513 rows=100 loops=1)
As seen in this example, when the query is an \texttt{INSERT}, \texttt{UPDATE}, or \texttt{DELETE} command, the actual work of applying the table changes is done by a top-level Insert, Update, or Delete plan node. The plan nodes underneath this node perform the work of locating the old rows and/or computing the new data. So above, we see the same sort of bitmap table scan we’ve seen already, and its output is fed to an Update node that stores the updated rows. It’s worth noting that although the data-modifying node can take a considerable amount of run time (here, it’s consuming the lion’s share of the time), the planner does not currently add anything to the cost estimates to account for that work. That’s because the work to be done is the same for every correct query plan, so it doesn’t affect planning decisions.

When an \texttt{UPDATE} or \texttt{DELETE} command affects an inheritance hierarchy, the output might look like this:

\begin{verbatim}
EXPLAIN UPDATE parent SET f2 = f2 + 1 WHERE f1 = 101;
QUERY PLAN

Update on parent  (cost=0.00..24.59 rows=0 width=0)
  Update on parent parent_1
  Update on child1 parent_2
  Update on child2 parent_3
  Update on child3 parent_4
  ->  Result  (cost=0.00..24.59 rows=4 width=14)
    ->  Append  (cost=0.00..24.54 rows=4 width=14)
      ->  Seq Scan on parent parent_1  (cost=0.00..0.00 rows=1 width=14)
        Filter: (f1 = 101)
      ->  Index Scan using child1_pkey on child1 parent_2  (cost=0.15..8.17 rows=1 width=14)
        Index Cond: (f1 = 101)
      ->  Index Scan using child2_pkey on child2 parent_3  (cost=0.15..8.17 rows=1 width=14)
        Index Cond: (f1 = 101)
      ->  Index Scan using child3_pkey on child3 parent_4  (cost=0.15..8.17 rows=1 width=14)
        Index Cond: (f1 = 101)

In this example the Update node needs to consider three child tables as well as the originally-mentioned parent table. So there are four input scanning subplans, one per table. For clarity, the Update node is annotated to show the specific target tables that will be updated, in the same order as the corresponding subplans.

The Planning time shown by \texttt{EXPLAIN ANALYZE} is the time it took to generate the query plan from the parsed query and optimize it. It does not include parsing or rewriting.

The Execution time shown by \texttt{EXPLAIN ANALYZE} includes executor start-up and shut-down time, as well as the time to run any triggers that are fired, but it does not include parsing, rewriting, or planning time. Time spent executing \texttt{BEFORE} triggers, if any, is included in the time for the related Insert, Update, or Delete node; but time spent executing \texttt{AFTER} triggers is not counted there because \texttt{AFTER} triggers are fired after completion of the whole plan. The total time spent in each trigger (either \texttt{BEFORE} or \texttt{AFTER}) is also shown separately. Note that deferred constraint triggers will not be executed until end of transaction and are thus not considered at all by \texttt{EXPLAIN ANALYZE}.
14.1.3. Caveats

There are two significant ways in which run times measured by `EXPLAIN ANALYZE` can deviate from normal execution of the same query. First, since no output rows are delivered to the client, network transmission costs and I/O conversion costs are not included. Second, the measurement overhead added by `EXPLAIN ANALYZE` can be significant, especially on machines with slow `gettimeofday()` operating-system calls. You can use the `pg_test_timing` tool to measure the overhead of timing on your system.

`EXPLAIN` results should not be extrapolated to situations much different from the one you are actually testing; for example, results on a toy-sized table cannot be assumed to apply to large tables. The planner’s cost estimates are not linear and so it might choose a different plan for a larger or smaller table. An extreme example is that on a table that only occupies one disk page, you’ll nearly always get a sequential scan plan whether indexes are available or not. The planner realizes that it's going to take one disk page read to process the table in any case, so there's no value in expending additional page reads to look at an index. (We saw this happening in the `polygon_tbl` example above.)

There are cases in which the actual and estimated values won't match up well, but nothing is really wrong. One such case occurs when plan node execution is stopped short by a `LIMIT` or similar effect. For example, in the `LIMIT` query we used before,

```
EXPLAIN ANALYZE SELECT * FROM tenk1 WHERE unique1 < 100 AND unique2 > 9000 LIMIT 2;
```

the estimated cost and row count for the Index Scan node are shown as though it were run to completion. But in reality the Limit node stopped requesting rows after it got two, so the actual row count is only 2 and the run time is less than the cost estimate would suggest. This is not an estimation error, only a discrepancy in the way the estimates and true values are displayed.

Merge joins also have measurement artifacts that can confuse the unwary. A merge join will stop reading one input if it's exhausted the other input and the next key value in the one input is greater than the last key value of the other input; in such a case there can be no more matches and so no need to scan the rest of the first input. This results in not reading all of one child, with results like those mentioned for `LIMIT`. Also, if the outer (first) child contains rows with duplicate key values, the inner (second) child is backed up and rescanned for the portion of its rows matching that key value. `EXPLAIN ANALYZE` counts these repeated emissions of the same inner rows as if they were real additional rows. When there are many outer duplicates, the reported actual row count for the inner child plan node can be significantly larger than the number of rows that are actually in the inner relation.

`BitmapAnd` and `BitmapOr` nodes always report their actual row counts as zero, due to implementation limitations.

Normally, `EXPLAIN` will display every plan node created by the planner. However, there are cases where the executor can determine that certain nodes need not be executed because they cannot produce any rows, based on parameter values that were not available at planning time. (Currently this can only happen for child nodes of an `Append` or `MergeAppend` node that is scanning a partitioned table.) When this happens, those plan nodes are omitted from the `EXPLAIN` output and a `Subplans Removed: N` annotation appears instead.

14.2. Statistics Used by the Planner
14.2.1. Single-Column Statistics

As we saw in the previous section, the query planner needs to estimate the number of rows retrieved by a query in order to make good choices of query plans. This section provides a quick look at the statistics that the system uses for these estimates.

One component of the statistics is the total number of entries in each table and index, as well as the number of disk blocks occupied by each table and index. This information is kept in the table `pg_class`, in the columns `reltuples` and `relpages`. We can look at it with queries similar to this one:

```sql
SELECT relname, relkind, reltuples, relpages
FROM pg_class
WHERE relname LIKE 'tenk1%';
```

<table>
<thead>
<tr>
<th>relname</th>
<th>relkind</th>
<th>reltuples</th>
<th>relpages</th>
</tr>
</thead>
<tbody>
<tr>
<td>tenk1</td>
<td>r</td>
<td>10000</td>
<td>358</td>
</tr>
<tr>
<td>tenk1_hundred</td>
<td>i</td>
<td>10000</td>
<td>30</td>
</tr>
<tr>
<td>tenk1_thous_tenthous</td>
<td>i</td>
<td>10000</td>
<td>30</td>
</tr>
<tr>
<td>tenk1_unique1</td>
<td>i</td>
<td>10000</td>
<td>30</td>
</tr>
<tr>
<td>tenk1_unique2</td>
<td>i</td>
<td>10000</td>
<td>30</td>
</tr>
</tbody>
</table>

(5 rows)

Here we can see that `tenk1` contains 10000 rows, as do its indexes, but the indexes are (unsurprisingly) much smaller than the table.

For efficiency reasons, `reltuples` and `relpages` are not updated on-the-fly, and so they usually contain somewhat out-of-date values. They are updated by `VACUUM`, `ANALYZE`, and a few DDL commands such as `CREATE INDEX`. A `VACUUM` or `ANALYZE` operation that does not scan the entire table (which is commonly the case) will incrementally update the `reltuples` count on the basis of the part of the table it did scan, resulting in an approximate value. In any case, the planner will scale the values it finds in `pg_class` to match the current physical table size, thus obtaining a closer approximation.

Most queries retrieve only a fraction of the rows in a table, due to `WHERE` clauses that restrict the rows to be examined. The planner thus needs to make an estimate of the selectivity of `WHERE` clauses, that is, the fraction of rows that match each condition in the `WHERE` clause. The information used for this task is stored in the `pg_statistic` system catalog. Entries in `pg_statistic` are updated by the `ANALYZE` and `VACUUM ANALYZE` commands, and are always approximate even when freshly updated.

Rather than look at `pg_statistic` directly, it's better to look at its view `pg_stats` when examining the statistics manually. `pg_stats` is designed to be more easily readable. Furthermore, `pg_stats` is readable by all, whereas `pg_statistic` is only readable by a superuser. (This prevents unprivileged users from learning something about the contents of other people's tables from the statistics. The `pg_stats` view is restricted to show only rows about tables that the current user can read.) For example, we might do:

```sql
SELECT attname, inherited, n_distinct,
       array_to_string(most_common_vals, E'\n') as most_common_vals
FROM pg_stats
WHERE tablename = 'road';
```

<table>
<thead>
<tr>
<th>attname</th>
<th>inherited</th>
<th>n_distinct</th>
<th>most_common_vals</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>f</td>
<td>-0.363388</td>
<td>I- 580 Ramp+</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>I- 880 Ramp+</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>Sp Railroad +</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>I- 580 +</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>I- 680 Ramp</td>
</tr>
<tr>
<td>name</td>
<td>t</td>
<td>-0.284859</td>
<td>I- 880 Ramp+</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>I- 580 Ramp+</td>
</tr>
</tbody>
</table>

436
Note that two rows are displayed for the same column, one corresponding to the complete inheritance hierarchy starting at the `road` table (inherited=t), and another one including only the `road` table itself (inherited=f).

The amount of information stored in `pg_statistic` by `ANALYZE`, in particular the maximum number of entries in the `most_common_vals` and `histogram_bounds` arrays for each column, can be set on a column-by-column basis using the `ALTER TABLE SET STATISTICS` command, or globally by setting the `default_statistics_target` configuration variable. The default limit is presently 100 entries. Raising the limit might allow more accurate planner estimates to be made, particularly for columns with irregular data distributions, at the price of consuming more space in `pg_statistic` and slightly more time to compute the estimates. Conversely, a lower limit might be sufficient for columns with simple data distributions.

Further details about the planner's use of statistics can be found in Chapter 67.

14.2.2. Extended Statistics

It is common to see slow queries running bad execution plans because multiple columns used in the query clauses are correlated. The planner normally assumes that multiple conditions are independent of each other, an assumption that does not hold when column values are correlated. Regular statistics, because of their per-individual-column nature, cannot capture any knowledge about cross-column correlation. However, Postgres Pro has the ability to compute multivariate statistics, which can capture such information.

Because the number of possible column combinations is very large, it's impractical to compute multivariate statistics automatically. Instead, extended statistics objects, more often called just statistics objects, can be created to instruct the server to obtain statistics across interesting sets of columns.

Statistics objects are created using the `CREATE STATISTICS` command. Creation of such an object merely creates a catalog entry expressing interest in the statistics. Actual data collection is performed by `ANALYZE` (either a manual command, or background auto-analyze). The collected values can be examined in the `pg_statistic_ext_data` catalog.

`ANALYZE` computes extended statistics based on the same sample of table rows that it takes for computing regular single-column statistics. Since the sample size is increased by increasing the statistics target for the table or any of its columns (as described in the previous section), a larger statistics target will normally result in more accurate extended statistics, as well as more time spent calculating them.

The following subsections describe the kinds of extended statistics that are currently supported.

14.2.2.1. Functional Dependencies

The simplest kind of extended statistics tracks functional dependencies, a concept used in definitions of database normal forms. We say that column $b$ is functionally dependent on column $a$ if knowledge of the value of $a$ is sufficient to determine the value of $b$, that is there are no two rows having the same value of $a$ but different values of $b$. In a fully normalized database, functional dependencies should exist only on primary keys and superkeys. However, in practice many data sets are not fully normalized for various reasons; intentional denormalization for performance reasons is a common example. Even in a fully normalized database, there may be partial correlation between some columns, which can be expressed as partial functional dependency.

The existence of functional dependencies directly affects the accuracy of estimates in certain queries. If a query contains conditions on both the independent and the dependent column(s), the conditions on the dependent columns do not further reduce the result size; but without knowledge of the functional dependency, the query planner will assume that the conditions are independent, resulting in underestimating the result size.
To inform the planner about functional dependencies, ANALYZE can collect measurements of cross-column dependency. Assessing the degree of dependency between all sets of columns would be prohibitively expensive, so data collection is limited to those groups of columns appearing together in a statistics object defined with the dependencies option. It is advisable to create dependencies statistics only for column groups that are strongly correlated, to avoid unnecessary overhead in both ANALYZE and later query planning.

Here is an example of collecting functional-dependency statistics:

```
CREATE STATISTICS stts (dependencies) ON city, zip FROM zipcodes;
ANALYZE zipcodes;
```

```
SELECT stxname, stxkeys, stxddependencies
FROM pg_statistic_ext join pg_statistic_ext_data on (oid = stxoid)
WHERE stxname = 'stts';
```

```
<table>
<thead>
<tr>
<th>stxname</th>
<th>stxkeys</th>
<th>stxddependencies</th>
</tr>
</thead>
<tbody>
<tr>
<td>stts</td>
<td>1 5</td>
<td>{&quot;1 =&gt; 5&quot;: 1.000000, &quot;5 =&gt; 1&quot;: 0.423130}</td>
</tr>
</tbody>
</table>
```

Here it can be seen that column 1 (zip code) fully determines column 5 (city) so the coefficient is 1.0, while city only determines zip code about 42% of the time, meaning that there are many cities (58%) that are represented by more than a single ZIP code.

When computing the selectivity for a query involving functionally dependent columns, the planner adjusts the per-condition selectivity estimates using the dependency coefficients so as not to produce an underestimate.

14.2.2.1. Limitations of Functional Dependencies

Functional dependencies are currently only applied when considering simple equality conditions that compare columns to constant values, and IN clauses with constant values. They are not used to improve estimates for equality conditions comparing two columns or comparing a column to an expression, nor for range clauses, LIKE or any other type of condition.

When estimating with functional dependencies, the planner assumes that conditions on the involved columns are compatible and hence redundant. If they are incompatible, the correct estimate would be zero rows, but that possibility is not considered. For example, given a query like

```
SELECT * FROM zipcodes WHERE city = 'San Francisco' AND zip = '94105';
```

the planner will disregard the `city` clause as not changing the selectivity, which is correct. However, it will make the same assumption about

```
SELECT * FROM zipcodes WHERE city = 'San Francisco' AND zip = '90210';
```

even though there will really be zero rows satisfying this query. Functional dependency statistics do not provide enough information to conclude that, however.

In many practical situations, this assumption is usually satisfied; for example, there might be a GUI in the application that only allows selecting compatible city and ZIP code values to use in a query. But if that's not the case, functional dependencies may not be a viable option.

14.2.2.2. Multivariate N-Distinct Counts

Single-column statistics store the number of distinct values in each column. Estimates of the number of distinct values when combining more than one column (for example, for GROUP BY a, b) are frequently wrong when the planner only has single-column statistical data, causing it to select bad plans.

To improve such estimates, ANALYZE can collect n-distinct statistics for groups of columns. As before, it's impractical to do this for every possible column grouping, so data is collected only for those groups...
Performance Tips

of columns appearing together in a statistics object defined with the \texttt{ndistinct} option. Data will be collected for each possible combination of two or more columns from the set of listed columns.

Continuing the previous example, the n-distinct counts in a table of ZIP codes might look like the following:

\begin{verbatim}
CREATE STATISTICS stts2 (ndistinct) ON city, state, zip FROM zipcodes;
ANALYZE zipcodes;
SELECT stxkeys AS k, stxdndistinct AS nd
    FROM pg_statistic_ext join pg_statistic_ext_data on (oid = stxoid)
    WHERE stxname = 'stts2';
\end{verbatim}

\begin{verbatim}
-\[ RECORD 1 \]--------------------------------------------------------
  k  | 1 2 5
  nd | {"1, 2": 33178, "1, 5": 33178, "2, 5": 27435, "1, 2, 5": 33178}
(1 row)
\end{verbatim}

This indicates that there are three combinations of columns that have 33178 distinct values: ZIP code and state; ZIP code and city; and ZIP code, city and state (the fact that they are all equal is expected given that ZIP code alone is unique in this table). On the other hand, the combination of city and state has only 27435 distinct values.

It's advisable to create \texttt{ndistinct} statistics objects only on combinations of columns that are actually used for grouping, and for which misestimation of the number of groups is resulting in bad plans. Otherwise, the \texttt{ANALYZE} cycles are just wasted.

\subsection{14.2.2.3. Multivariate MCV Lists}

Another type of statistics stored for each column are most-common value lists. This allows very accurate estimates for individual columns, but may result in significant misestimates for queries with conditions on multiple columns.

To improve such estimates, \texttt{ANALYZE} can collect MCV lists on combinations of columns. Similarly to functional dependencies and n-distinct coefficients, it's impractical to do this for every possible column grouping. Even more so in this case, as the MCV list (unlike functional dependencies and n-distinct coefficients) does store the common column values. So data is collected only for those groups of columns appearing together in a statistics object defined with the \texttt{mcv} option.

Continuing the previous example, the MCV list for a table of ZIP codes might look like the following (unlike for simpler types of statistics, a function is required for inspection of MCV contents):

\begin{verbatim}
CREATE STATISTICS stts3 (mcv) ON city, state FROM zipcodes;
ANALYZE zipcodes;
SELECT m.* FROM pg_statistic_ext join pg_statistic_ext_data on (oid = stxoid),
    pg_mcv_list_items(stxdmcv) m WHERE stxname = 'stts3';
\end{verbatim}

\begin{verbatim}
index | values         | nulls | frequency | base_frequency
-------+----------------+-------+-----------+----------------
 0     | {Washington, DC} | {f,f} | 0.003467  | 2.7e-05
 1     | {Apo, AE}       | {f,f} | 0.003067  | 1.9e-05
 2     | {Houston, TX}   | {f,f} | 0.002167  | 0.000133
 3     | {El Paso, TX}   | {f,f} | 0.002     | 0.000113
 4     | {New York, NY}  | {f,f} | 0.001967  | 0.000114
 5     | {Atlanta, GA}   | {f,f} | 0.001633  | 0.000114
 6     | {Sacramento, CA} | {f,f} | 0.001433  | 3.3e-05
 7     | {Miami, FL}     | {f,f} | 0.001433  | 7.8e-05
 8     | {Dallas, TX}    | {f,f} | 0.001367  | 5.1e-05
 9     | {Chicago, IL}   | {f,f} | 0.001367  | 8.8e-05
\end{verbatim}
Performance Tips

... (99 rows)

This indicates that the most common combination of city and state is Washington in DC, with actual frequency (in the sample) about 0.35%. The base frequency of the combination (as computed from the simple per-column frequencies) is only 0.0027%, resulting in two orders of magnitude under-estimates.

It's advisable to create MCV statistics objects only on combinations of columns that are actually used in conditions together, and for which misestimation of the number of groups is resulting in bad plans. Otherwise, the ANALYZE and planning cycles are just wasted.

14.3. Controlling the Planner with Explicit JOIN Clauses

It is possible to control the query planner to some extent by using the explicit JOIN syntax. To see why this matters, we first need some background.

In a simple join query, such as:

```
SELECT * FROM a, b, c WHERE a.id = b.id AND b.ref = c.id;
```

the planner is free to join the given tables in any order. For example, it could generate a query plan that joins A to B, using the WHERE condition `a.id = b.id`, and then joins C to this joined table, using the other WHERE condition. Or it could join B to C and then join A to that result. Or it could join A to C and then join them with B — but that would be inefficient, since the full Cartesian product of A and C would have to be formed, there being no applicable condition in the WHERE clause to allow optimization of the join. (All joins in the Postgres Pro executor happen between two input tables, so it’s necessary to build up the result in one or another of these fashions.) The important point is that these different join possibilities give semantically equivalent results but might have hugely different execution costs. Therefore, the planner will explore all of them to try to find the most efficient query plan.

When a query only involves two or three tables, there aren't many join orders to worry about. But the number of possible join orders grows exponentially as the number of tables expands. Beyond ten or so input tables it's no longer practical to do an exhaustive search of all the possibilities, and even for six or seven tables planning might take an annoyingly long time. When there are too many input tables, the Postgres Pro planner will switch from exhaustive search to a genetic probabilistic search through a limited number of possibilities. (The switch-over threshold is set by the geqo_threshold runtime parameter.) The genetic search takes less time, but it won't necessarily find the best possible plan.

When the query involves outer joins, the planner has less freedom than it does for plain (inner) joins. For example, consider:

```
SELECT * FROM a LEFT JOIN (b JOIN c ON (b.ref = c.id)) ON (a.id = b.id);
```

Although this query's restrictions are superficially similar to the previous example, the semantics are different because a row must be emitted for each row of A that has no matching row in the join of B and C. Therefore the planner has no choice of join order here: it must join B to C and then join A to that result. Accordingly, this query takes less time to plan than the previous query. In other cases, the planner might be able to determine that more than one join order is safe. For example, given:

```
SELECT * FROM a LEFT JOIN b ON (a.bid = b.id) LEFT JOIN c ON (a.cid = c.id);
```

it is valid to join A to either B or C first. Currently, only FULL JOIN completely constrains the join order. Most practical cases involving LEFT JOIN or RIGHT JOIN can be rearranged to some extent.

Explicit inner join syntax (INNER JOIN, CROSS JOIN, or unadorned JOIN) is semantically the same as listing the input relations in FROM, so it does not constrain the join order.

Even though most kinds of JOIN don’t completely constrain the join order, it is possible to instruct the Postgres Pro query planner to treat all JOIN clauses as constraining the join order anyway. For example, these three queries are logically equivalent:

```
SELECT * FROM a, b, c WHERE a.id = b.id AND b.ref = c.id;
SELECT * FROM a CROSS JOIN b CROSS JOIN c WHERE a.id = b.id AND b.ref = c.id;
SELECT * FROM a, b, c WHERE a.id = b.id AND b.ref = c.id;
```
SELECT * FROM a JOIN (b JOIN c ON (b.ref = c.id)) ON (a.id = b.id);

But if we tell the planner to honor the JOIN order, the second and third take less time to plan than the first. This effect is not worth worrying about for only three tables, but it can be a lifesaver with many tables.

To force the planner to follow the join order laid out by explicit JOINs, set the join_collapse_limit runtime parameter to 1. (Other possible values are discussed below.)

You do not need to constrain the join order completely in order to cut search time, because it’s OK to use JOIN operators within items of a plain FROM list. For example, consider:

SELECT * FROM a CROSS JOIN b, c, d, e WHERE ...;

With join_collapse_limit = 1, this forces the planner to join A to B before joining them to other tables, but doesn't constrain its choices otherwise. In this example, the number of possible join orders is reduced by a factor of 5.

Constraining the planner's search in this way is a useful technique both for reducing planning time and for directing the planner to a good query plan. If the planner chooses a bad join order by default, you can force it to choose a better order via JOIN syntax — assuming that you know of a better order, that is. Experimentation is recommended.

A closely related issue that affects planning time is collapsing of subqueries into their parent query. For example, consider:

SELECT * 
FROM x, y, 
     (SELECT * FROM a, b, c WHERE something) AS ss 
WHERE somethingelse;

This situation might arise from use of a view that contains a join; the view's SELECT rule will be inserted in place of the view reference, yielding a query much like the above. Normally, the planner will try to collapse the subquery into the parent, yielding:

SELECT * FROM x, y, a, b, c WHERE something AND somethingelse;

This usually results in a better plan than planning the subquery separately. (For example, the outer WHERE conditions might be such that joining X to A first eliminates many rows of A, thus avoiding the need to form the full logical output of the subquery.) But at the same time, we have increased the planning time; here, we have a five-way join problem replacing two separate three-way join problems. Because of the exponential growth of the number of possibilities, this makes a big difference. The planner tries to avoid getting stuck in huge join search problems by not collapsing a subquery if more than from_collapse_limit FROM items would result in the parent query. You can trade off planning time against quality of plan by adjusting this run-time parameter up or down.

from_collapse_limit and join_collapse_limit are similarly named because they do almost the same thing: one controls when the planner will “flatten out” subqueries, and the other controls when it will flatten out explicit joins. Typically you would either set join_collapse_limit equal to from_collapse_limit (so that explicit joins and subqueries act similarly) or set join_collapse_limit to 1 (if you want to control join order with explicit joins). But you might set them differently if you are trying to fine-tune the trade-off between planning time and run time.

14.4. Populating a Database

One might need to insert a large amount of data when first populating a database. This section contains some suggestions on how to make this process as efficient as possible.

14.4.1. Disable Autocommit

When using multiple INSERTs, turn off autocommit and just do one commit at the end. (In plain SQL, this means issuing BEGIN at the start and COMMIT at the end. Some client libraries might do this behind your back, in which case you need to make sure the library does it when you want it done.) If you allow each insertion to be committed separately, Postgres Pro is doing a lot of work for each row that is added. An
additional benefit of doing all insertions in one transaction is that if the insertion of one row were to fail then the insertion of all rows inserted up to that point would be rolled back, so you won't be stuck with partially loaded data.

14.4.2. Use COPY

Use COPY to load all the rows in one command, instead of using a series of INSERT commands. The COPY command is optimized for loading large numbers of rows; it is less flexible than INSERT, but incurs significantly less overhead for large data loads. Since COPY is a single command, there is no need to disable autocommit if you use this method to populate a table.

If you cannot use COPY, it might help to use PREPARE to create a prepared INSERT statement, and then use EXECUTE as many times as required. This avoids some of the overhead of repeatedly parsing and planning INSERT. Different interfaces provide this facility in different ways; look for “prepared statements” in the interface documentation.

Note that loading a large number of rows using COPY is almost always faster than using INSERT, even if PREPARE is used and multiple insertions are batched into a single transaction.

COPY is fastest when used within the same transaction as an earlier CREATE TABLE or TRUNCATE command. In such cases no WAL needs to be written, because in case of an error, the files containing the newly loaded data will be removed anyway. However, this consideration only applies when wal_level is minimal as all commands must write WAL otherwise.

14.4.3. Remove Indexes

If you are loading a freshly created table, the fastest method is to create the table, bulk load the table’s data using COPY, then create any indexes needed for the table. Creating an index on pre-existing data is quicker than updating it incrementally as each row is loaded.

If you are adding large amounts of data to an existing table, it might be a win to drop the indexes, load the table, and then recreate the indexes. Of course, the database performance for other users might suffer during the time the indexes are missing. One should also think twice before dropping a unique index, since the error checking afforded by the unique constraint will be lost while the index is missing.

14.4.4. Remove Foreign Key Constraints

Just as with indexes, a foreign key constraint can be checked “in bulk” more efficiently than row-by-row. So it might be useful to drop foreign key constraints, load data, and re-create the constraints. Again, there is a trade-off between data load speed and loss of error checking while the constraint is missing.

What’s more, when you load data into a table with existing foreign key constraints, each new row requires an entry in the server’s list of pending trigger events (since it is the firing of a trigger that checks the row’s foreign key constraint). Loading many millions of rows can cause the trigger event queue to overflow available memory, leading to intolerable swapping or even outright failure of the command. Therefore it may be necessary, not just desirable, to drop and re-apply foreign keys when loading large amounts of data. If temporarily removing the constraint isn’t acceptable, the only other recourse may be to split up the load operation into smaller transactions.

14.4.5. Increase maintenance_work_mem

Temporarily increasing the maintenance_work_mem configuration variable when loading large amounts of data can lead to improved performance. This will help to speed up CREATE INDEX commands and ALTER TABLE ADD FOREIGN KEY commands. It won’t do much for COPY itself, so this advice is only useful when you are using one or both of the above techniques.

14.4.6. Increase max_wal_size

Temporarily increasing the max_wal_size configuration variable can also make large data loads faster. This is because loading a large amount of data into Postgres Pro will cause checkpoints to occur
more often than the normal checkpoint frequency (specified by the `checkpoint_timeout` configuration variable). Whenever a checkpoint occurs, all dirty pages must be flushed to disk. By increasing `max_wal_size` temporarily during bulk data loads, the number of checkpoints that are required can be reduced.

### 14.4.7. Disable WAL Archival and Streaming Replication

When loading large amounts of data into an installation that uses WAL archiving or streaming replication, it might be faster to take a new base backup after the load has completed than to process a large amount of incremental WAL data. To prevent incremental WAL logging while loading, disable archiving and streaming replication, by setting `wal_level` to `minimal`, `archive_mode` to `off`, and `max_wal_senders` to zero. But note that changing these settings requires a server restart, and makes any base backups taken before unavailable for archive recovery and standby server, which may lead to data loss.

Aside from avoiding the time for the archiver or WAL sender to process the WAL data, doing this will actually make certain commands faster, because they do not to write WAL at all if `wal_level` is `minimal` and the current subtransaction (or top-level transaction) created or truncated the table or index they change. (They can guarantee crash safety more cheaply by doing an `fsync` at the end than by writing WAL.)

### 14.4.8. Run `ANALYZE` Afterwards

Whenever you have significantly altered the distribution of data within a table, running `ANALYZE` is strongly recommended. This includes bulk loading large amounts of data into the table. Running `ANALYZE` (or `VACUUM ANALYZE`) ensures that the planner has up-to-date statistics about the table. With no statistics or obsolete statistics, the planner might make poor decisions during query planning, leading to poor performance on any tables with inaccurate or nonexistent statistics. Note that if the autovacuum daemon is enabled, it might run `ANALYZE` automatically; see Section 23.1.3 and Section 23.1.6 for more information.

### 14.4.9. Some Notes about `pg_dump`

Dump scripts generated by `pg_dump` automatically apply several, but not all, of the above guidelines. To reload a `pg_dump` dump as quickly as possible, you need to do a few extra things manually. (Note that these points apply while restoring a dump, not while creating it. The same points apply whether loading a text dump with `psql` or using `pg_restore` to load from a `pg_dump` archive file.)

By default, `pg_dump` uses `COPY`, and when it is generating a complete schema-and-data dump, it is careful to load data before creating indexes and foreign keys. So in this case several guidelines are handled automatically. What is left for you to do is to:

- Set appropriate (i.e., larger than normal) values for `maintenance_work_mem` and `max_wal_size`.
- If using WAL archiving or streaming replication, consider disabling them during the restore. To do that, set `archive_mode` to `off`, `wal_level` to `minimal`, and `max_wal_senders` to zero before loading the dump. Afterwards, set them back to the right values and take a fresh base backup.
- Experiment with the parallel dump and restore modes of both `pg_dump` and `pg_restore` and find the optimal number of concurrent jobs to use. Dumping and restoring in parallel by means of the `-j` option should give you a significantly higher performance over the serial mode.
- Consider whether the whole dump should be restored as a single transaction. To do that, pass the `-1` or `--single-transaction` command-line option to `psql` or `pg_restore`. When using this mode, even the smallest of errors will rollback the entire restore, possibly discarding many hours of processing. Depending on how interrelated the data is, that might seem preferable to manual cleanup, or not. `COPY` commands will run fastest if you use a single transaction and have WAL archiving turned off.
- If multiple CPUs are available in the database server, consider using `pg_restore`'s `--jobs` option. This allows concurrent data loading and index creation.
- Run `ANALYZE` afterwards.
Performance Tips

A data-only dump will still use COPY, but it does not drop or recreate indexes, and it does not normally touch foreign keys. So when loading a data-only dump, it is up to you to drop and recreate indexes and foreign keys if you wish to use those techniques. It's still useful to increase max_wal_size while loading the data, but don't bother increasing maintenance_work_mem; rather, you'd do that while manually recreating indexes and foreign keys afterwards. And don't forget to ANALYZE when you're done; see Section 23.1.3 and Section 23.1.6 for more information.

14.5. Non-Durable Settings

Durability is a database feature that guarantees the recording of committed transactions even if the server crashes or loses power. However, durability adds significant database overhead, so if your site does not require such a guarantee, Postgres Pro can be configured to run much faster. The following are configuration changes you can make to improve performance in such cases. Except as noted below, durability is still guaranteed in case of a crash of the database software; only an abrupt operating system crash creates a risk of data loss or corruption when these settings are used.

- Place the database cluster's data directory in a memory-backed file system (i.e., RAM disk). This eliminates all database disk I/O, but limits data storage to the amount of available memory (and perhaps swap).
- Turn off fsync; there is no need to flush data to disk.
- Turn off synchronous_commit; there might be no need to force WAL writes to disk on every commit. This setting does risk transaction loss (though not data corruption) in case of a crash of the database.
- Turn off full_page_writes; there is no need to guard against partial page writes.
- Increase max_wal_size and checkpoint_timeout; this reduces the frequency of checkpoints, but increases the storage requirements of /pg_wal.
- Create unlogged tables to avoid WAL writes, though it makes the tables non-crash-safe.

---

1 You can get the effect of disabling foreign keys by using the --disable-triggers option — but realize that that eliminates, rather than just postpones, foreign key validation, and so it is possible to insert bad data if you use it.
Chapter 15. Parallel Query

Postgres Pro can devise query plans that can leverage multiple CPUs in order to answer queries faster. This feature is known as parallel query. Many queries cannot benefit from parallel query, either due to limitations of the current implementation or because there is no imaginable query plan that is any faster than the serial query plan. However, for queries that can benefit, the speedup from parallel query is often very significant. Many queries can run more than twice as fast when using parallel query, and some queries can run four times faster or even more. Queries that touch a large amount of data but return only a few rows to the user will typically benefit most. This chapter explains some details of how parallel query works and in which situations it can be used so that users who wish to make use of it can understand what to expect.

15.1. How Parallel Query Works

When the optimizer determines that parallel query is the fastest execution strategy for a particular query, it will create a query plan that includes a Gather or Gather Merge node. Here is a simple example:

```sql
EXPLAIN SELECT * FROM pgbench_accounts WHERE filler LIKE '%x%';
```

```
QUERY PLAN
-------------------------------------------------------------------------------------
Gather  (cost=1000.00..217018.43 rows=1 width=97)
Workers Planned: 2
  ->  Parallel Seq Scan on pgbench_accounts  (cost=0.00..216018.33 rows=1 width=97)
      Filter: (filler ~~ '%x%':text)
(4 rows)
```

In all cases, the Gather or Gather Merge node will have exactly one child plan, which is the portion of the plan that will be executed in parallel. If the Gather or Gather Merge node is at the very top of the plan tree, then the entire query will execute in parallel. If it is somewhere else in the plan tree, then only the portion of the plan below it will run in parallel. In the example above, the query accesses only one table, so there is only one plan node other than the Gather node itself; since that plan node is a child of the Gather node, it will run in parallel.

Using EXPLAIN, you can see the number of workers chosen by the planner. When the Gather node is reached during query execution, the process that is implementing the user’s session will request a number of background worker processes equal to the number of workers chosen by the planner. The number of background workers that the planner will consider using is limited to at most max_parallel_workers_per_gather. The total number of background workers that can exist at any one time is limited by both max_worker_processes and max_parallel_workers. Therefore, it is possible for a parallel query to run with fewer workers than planned, or even with no workers at all. The optimal plan may depend on the number of workers that are available, so this can result in poor query performance. If this occurrence is frequent, consider increasing max_worker_processes and max_parallel_workers so that more workers can be run simultaneously or alternatively reducing max_parallel_workers_per_gather so that the planner requests fewer workers.

Every background worker process that is successfully started for a given parallel query will execute the parallel portion of the plan. The leader will also execute that portion of the plan, but it has an additional responsibility: it must also read all of the tuples generated by the workers. When the parallel portion of the plan generates only a small number of tuples, the leader will often behave very much like an additional worker, speeding up query execution. Conversely, when the parallel portion of the plan generates a large number of tuples, the leader may be almost entirely occupied with reading the tuples generated by the workers and performing any further processing steps that are required by plan nodes above the level of the Gather node or Gather Merge node. In such cases, the leader will do very little of the work of executing the parallel portion of the plan.

When the node at the top of the parallel portion of the plan is Gather Merge rather than Gather, it indicates that each process executing the parallel portion of the plan is producing tuples in sorted order, and that the leader is performing an order-preserving merge. In contrast, Gather reads tuples from the workers in whatever order is convenient, destroying any sort order that may have existed.
15.2. When Can Parallel Query Be Used?

There are several settings that can cause the query planner not to generate a parallel query plan under any circumstances. In order for any parallel query plans whatsoever to be generated, the following settings must be configured as indicated.

- `max_parallel_workers_per_gather` must be set to a value that is greater than zero. This is a special case of the more general principle that no more workers should be used than the number configured via `max_parallel_workers_per_gather`.

In addition, the system must not be running in single-user mode. Since the entire database system is running in single process in this situation, no background workers will be available.

Even when it is in general possible for parallel query plans to be generated, the planner will not generate them for a given query if any of the following are true:

- The query writes any data or locks any database rows. If a query contains a data-modifying operation either at the top level or within a CTE, no parallel plans for that query will be generated. As an exception, the following commands, which create a new table and populate it, can use a parallel plan for the underlying `SELECT` part of the query:
  - `CREATE TABLE ... AS`
  - `SELECT INTO`
  - `CREATE MATERIALIZED VIEW`
  - `REFRESH MATERIALIZED VIEW`

- The query might be suspended during execution. In any situation in which the system thinks that partial or incremental execution might occur, no parallel plan is generated. For example, a cursor created using `DECLARE CURSOR` will never use a parallel plan. Similarly, a PL/pgSQL loop of the form `FOR x IN query LOOP .. END LOOP` will never use a parallel plan, because the parallel query system is unable to verify that the code in the loop is safe to execute while parallel query is active.

- The query uses any function marked `PARALLEL UNSAFE`. Most system-defined functions are `PARALLEL SAFE`, but user-defined functions are marked `PARALLEL UNSAFE` by default. See the discussion of Section 15.4.

- The query is running inside of another query that is already parallel. For example, if a function called by a parallel query issues an SQL query itself, that query will never use a parallel plan. This is a limitation of the current implementation, but it may not be desirable to remove this limitation, since it could result in a single query using a very large number of processes.

Even when parallel query plan is generated for a particular query, there are several circumstances under which it will be impossible to execute that plan in parallel at execution time. If this occurs, the leader will execute the portion of the plan below the `Gather` node entirely by itself, almost as if the `Gather` node were not present. This will happen if any of the following conditions are met:

- No background workers can be obtained because of the limitation that the total number of background workers cannot exceed `max_worker_processes`.

- No background workers can be obtained because of the limitation that the total number of background workers launched for purposes of parallel query cannot exceed `max_parallel_workers`.

- The client sends an Execute message with a non-zero fetch count. See the discussion of the extended query protocol. Since `libpq` currently provides no way to send such a message, this can only occur when using a client that does not rely on `libpq`. If this is a frequent occurrence, it may be a good idea to set `max_parallel_workers_per_gather` to zero in sessions where it is likely, so as to avoid generating query plans that may be suboptimal when run serially.

15.3. Parallel Plans

Because each worker executes the parallel portion of the plan to completion, it is not possible to simply take an ordinary query plan and run it using multiple workers. Each worker would produce a full copy
Parallel Query

of the output result set, so the query would not run any faster than normal but would produce incorrect results. Instead, the parallel portion of the plan must be what is known internally to the query optimizer as a partial plan; that is, it must be constructed so that each process that executes the plan will generate only a subset of the output rows in such a way that each required output row is guaranteed to be generated by exactly one of the cooperating processes. Generally, this means that the scan on the driving table of the query must be a parallel-aware scan.

15.3.1. Parallel Scans

The following types of parallel-aware table scans are currently supported.

- In a parallel sequential scan, the table's blocks will be divided among the cooperating processes. Blocks are handed out one at a time, so that access to the table remains sequential.
- In a parallel bitmap heap scan, one process is chosen as the leader. That process performs a scan of one or more indexes and builds a bitmap indicating which table blocks need to be visited. These blocks are then divided among the cooperating processes as in a parallel sequential scan. In other words, the heap scan is performed in parallel, but the underlying index scan is not.
- In a parallel index scan or parallel index-only scan, the cooperating processes take turns reading data from the index. Currently, parallel index scans are supported only for btree indexes. Each process will claim a single index block and will scan and return all tuples referenced by that block; other processes can at the same time be returning tuples from a different index block. The results of a parallel btree scan are returned in sorted order within each worker process.

Other scan types, such as scans of non-btree indexes, may support parallel scans in the future.

15.3.2. Parallel Joins

Just as in a non-parallel plan, the driving table may be joined to one or more other tables using a nested loop, hash join, or merge join. The inner side of the join may be any kind of non-parallel plan that is otherwise supported by the planner provided that it is safe to run within a parallel worker. Depending on the join type, the inner side may also be a parallel plan.

- In a nested loop join, the inner side is always non-parallel. Although it is executed in full, this is efficient if the inner side is an index scan, because the outer tuples and thus the loops that look up values in the index are divided over the cooperating processes.
- In a merge join, the inner side is always a non-parallel plan and therefore executed in full. This may be inefficient, especially if a sort must be performed, because the work and resulting data are duplicated in every cooperating process.
- In a hash join (without the "parallel" prefix), the inner side is executed in full by every cooperating process to build identical copies of the hash table. This may be inefficient if the hash table is large or the plan is expensive. In a parallel hash join, the inner side is a parallel hash that divides the work of building a shared hash table over the cooperating processes.

15.3.3. Parallel Aggregation

Postgres Pro supports parallel aggregation by aggregating in two stages. First, each process participating in the parallel portion of the query performs an aggregation step, producing a partial result for each group of which that process is aware. This is reflected in the plan as a Partial Aggregate node. Second, the partial results are transferred to the leader via Gather or Gather Merge. Finally, the leader re-aggregates the results across all workers in order to produce the final result. This is reflected in the plan as a Finalize Aggregate node.

Because the Finalize Aggregate node runs on the leader process, queries that produce a relatively large number of groups in comparison to the number of input rows will appear less favorable to the query planner. For example, in the worst-case scenario the number of groups seen by the Finalize Aggregate node could be as many as the number of input rows that were seen by all worker processes in the Partial Aggregate stage. For such cases, there is clearly going to be no performance benefit to using parallel aggregation. The query planner takes this into account during the planning process and is unlikely to choose parallel aggregate in this scenario.
Parallel aggregation is not supported in all situations. Each aggregate must be safe for parallelism and must have a combine function. If the aggregate has a transition state of type internal, it must have serialization and deserialization functions. See CREATE AGGREGATE for more details. Parallel aggregation is not supported if any aggregate function call contains DISTINCT or ORDER BY clause and is also not supported for ordered set aggregates or when the query involves GROUPING SETS. It can only be used when all joins involved in the query are also part of the parallel portion of the plan.

15.3.4. Parallel Append

Whenever Postgres Pro needs to combine rows from multiple sources into a single result set, it uses an Append or MergeAppend plan node. This commonly happens when implementing UNION ALL or when scanning a partitioned table. Such nodes can be used in parallel plans just as they can in any other plan. However, in a parallel plan, the planner may instead use a Parallel Append node.

When an Append node is used in a parallel plan, each process will execute the child plans in the order in which they appear, so that all participating processes cooperate to execute the first child plan until it is complete and then move to the second plan at around the same time. When a Parallel Append is used instead, the executor will instead spread out the participating processes as evenly as possible across its child plans, so that multiple child plans are executed simultaneously. This avoids contention, and also avoids paying the startup cost of a child plan in those processes that never execute it.

Also, unlike a regular Append node, which can only have partial children when used within a parallel plan, a Parallel Append node can have both partial and non-partial child plans. Non-partial children will be scanned by only a single process, since scanning them more than once would produce duplicate results. Plans that involve appending multiple results sets can therefore achieve coarse-grained parallelism even when efficient partial plans are not available. For example, consider a query against a partitioned table that can only be implemented efficiently by using an index that does not support parallel scans. The planner might choose a Parallel Append of regular Index Scan plans; each individual index scan would have to be executed to completion by a single process, but different scans could be performed at the same time by different processes.

enable_parallel_append can be used to disable this feature.

15.3.5. Parallel Plan Tips

If a query that is expected to do so does not produce a parallel plan, you can try reducing parallel_setup_cost or parallel_tuple_cost. Of course, this plan may turn out to be slower than the serial plan that the planner preferred, but this will not always be the case. If you don't get a parallel plan even with very small values of these settings (e.g., after setting them both to zero), there may be some reason why the query planner is unable to generate a parallel plan for your query. See Section 15.2 and Section 15.4 for information on why this may be the case.

When executing a parallel plan, you can use EXPLAIN (ANALYZE, VERBOSEx) to display per-worker statistics for each plan node. This may be useful in determining whether the work is being evenly distributed between all plan nodes and more generally in understanding the performance characteristics of the plan.

15.4. Parallel Safety

The planner classifies operations involved in a query as either parallel safe, parallel restricted, or parallel unsafe. A parallel safe operation is one that does not conflict with the use of parallel query. A parallel restricted operation is one that cannot be performed in a parallel worker, but that can be performed in the leader while parallel query is in use. Therefore, parallel restricted operations can never occur below a Gather or Gather Merge node, but can occur elsewhere in a plan that contains such a node. A parallel unsafe operation is one that cannot be performed while parallel query is in use, not even in the leader. When a query contains anything that is parallel unsafe, parallel query is completely disabled for that query.

The following operations are always parallel restricted:
• Scans of common table expressions (CTEs).
• Scans of temporary tables.
• Scans of foreign tables, unless the foreign data wrapper has an IsForeignScanParallelSafe API that indicates otherwise.
• Plan nodes to which an InitPlan is attached.
• Plan nodes that reference a correlated SubPlan.

15.4.1. Parallel Labeling for Functions and Aggregates

The planner cannot automatically determine whether a user-defined function or aggregate is parallel safe, parallel restricted, or parallel unsafe, because this would require predicting every operation that the function could possibly perform. In general, this is equivalent to the Halting Problem and therefore impossible. Even for simple functions where it could conceivably be done, we do not try, since this would be expensive and error-prone. Instead, all user-defined functions are assumed to be parallel unsafe unless otherwise marked. When using CREATE FUNCTION or ALTER FUNCTION, markings can be set by specifying PARALLEL SAFE, PARALLEL RESTRICTED, or PARALLEL UNSAFE as appropriate. When using CREATE AGGREGATE, the PARALLEL option can be specified with SAFE, RESTRICTED, or UNSAFE as the corresponding value.

Functions and aggregates must be marked PARALLEL UNSAFE if they write to the database, access sequences, change the transaction state even temporarily (e.g., a PL/pgSQL function that establishes an EXCEPTION block to catch errors), or make persistent changes to settings. Similarly, functions must be marked PARALLEL RESTRICTED if they access temporary tables, client connection state, cursors, prepared statements, or miscellaneous backend-local state that the system cannot synchronize across workers. For example, setseed and random are parallel restricted for this last reason.

In general, if a function is labeled as being safe when it is restricted or unsafe, or if it is labeled as being restricted when it is in fact unsafe, it may throw errors or produce wrong answers when used in a parallel query. C-language functions could in theory exhibit totally undefined behavior if mislabeled, since there is no way for the system to protect itself against arbitrary C code, but in most likely cases the result will be no worse than for any other function. If in doubt, it is probably best to label functions as UNSAFE.

If a function executed within a parallel worker acquires locks that are not held by the leader, for example by querying a table not referenced in the query, those locks will be released at worker exit, not end of transaction. If you write a function that does this, and this behavior difference is important to you, mark such functions as PARALLEL RESTRICTED to ensure that they execute only in the leader.

Note that the query planner does not consider deferring the evaluation of parallel-restricted functions or aggregates involved in the query in order to obtain a superior plan. So, for example, if a WHERE clause applied to a particular table is parallel restricted, the query planner will not consider performing a scan of that table in the parallel portion of a plan. In some cases, it would be possible (and perhaps even efficient) to include the scan of that table in the parallel portion of the query and defer the evaluation of the WHERE clause so that it happens above the Gather node. However, the planner does not do this.
Part III. Server Administration

This part covers topics that are of interest to a Postgres Pro database administrator. This includes installation of the software, set up and configuration of the server, management of users and databases, and maintenance tasks. Anyone who runs a Postgres Pro server, even for personal use, but especially in production, should be familiar with the topics covered in this part.

The information in this part is arranged approximately in the order in which a new user should read it. But the chapters are self-contained and can be read individually as desired. The information in this part is presented in a narrative fashion in topical units. Readers looking for a complete description of a particular command should see Part VI.

The first few chapters are written so they can be understood without prerequisite knowledge, so new users who need to set up their own server can begin their exploration with this part. The rest of this part is about tuning and management; that material assumes that the reader is familiar with the general use of the Postgres Pro database system. Readers are encouraged to look at Part I and Part II for additional information.
Chapter 16. Binary Installation

16.1. Installing Postgres Pro Standard on Linux

For Linux-based operating systems, Postgres Pro Standard is shipped as binary packages. Each Postgres Pro binary distribution consists of several packages. The package structure differs from vanilla PostgreSQL and offers the following installation modes:

- **Quick installation and setup.** The `postgrespro-std-14` package installs and configures all the components required for a viable ready-to-use configuration of both server and client components. Choose this option if you are going to install a single Postgres Pro instance only, and you are not worried about possible conflicts with other PostgreSQL-based products.

```
Important

Installing the `postgrespro-std-14` package can delete existing installations of Postgres Pro and PostgreSQL-based products. Similarly, this Postgres Pro installation may be automatically removed if you later install another PostgreSQL-based product. Do not use this package for upgrades or migrations, or if you are going to maintain several installations on the same system.
```

- **Custom installation.** You can select any packages required for your purposes, including development packages. This option needs manual configuration, so a good grasp of Linux and understanding of PostgreSQL architecture are required. This is the only option to choose if you are going to use Postgres Pro in one of the following scenarios:
  - Install several Postgres Pro versions side by side, or together with other PostgreSQL-based products.
  - Perform an upgrade from a previous version, or migrate from a different PostgreSQL-based product.
  - Control Postgres Pro server execution using high availability software, such as pacemaker, instead of the standard system service management facility.

The minimum hardware required to install Postgres Pro, create a database cluster and start the database server are as follows:

- 1-GHz processor
- 1 GB of RAM
- 1 GB of disk space

Additional disk space is required for data or supporting components.

16.1.1. Supported Linux Distributions

Postgres Pro binary packages are available for the following Linux-based systems:

- ALT Linux 8/9/10, ALT Linux 8 SP, ALT Linux 8.2 SP
- SUSE Linux Enterprise Server (SLES) 12/15
- OSnova 2.0
Binary Installation

**Note**

Postgres Pro binary packages rely on the tzdata library provided by the operating system, so you must ensure that the latest available version is installed. If tzdata is outdated, the time in your database may be incorrect.

### 16.1.2. Quick Installation and Setup

If you only need to install a single Postgres Pro instance and are not going to use any other PostgreSQL-based products on your system, you can use the quick installation mode. The typical process is as follows:

1. Add the package repository required for your operating system. You can find the exact repositories and commands for each supported Linux distribution on the [Download page](#) for the selected Postgres Pro version.

2. Install the `postgrespro-std-14` package. It will bring all the required components via dependencies, create the default database, start the database server, as well as enable server autostart at system boot and make all the provided programs available in PATH.

**Note**

By default, the database configuration is set for the Postgres Pro product being installed. If you need your database configured for a different product, choose custom installation and use the `tune` argument of the `pg-setup initdb` command.

Once the installation completes, you can launch `psql` on behalf of the `postgres` user and connect to the newly created database, which is located in the `/var/lib/pgpro/std-14/data` directory.

Since the default database is created using the `pg-setup` script, the path to its data directory is stored in the `/etc/default/postgrespro-std-14` file. All the subsequent `pg-setup` commands, as well as any commands that manage Postgres Pro service, affect this database only.

### 16.1.3. Custom Installation

Splitting the distribution into multiple packages enables customizing the installation for different purposes: database servers, client systems, or development workstations. Custom installations need to be configured manually, but give you more flexibility in using the product. You can install several Postgres Pro versions side by side, as well as together with other PostgreSQL-based products. In particular, this may be required when performing upgrades, or migrating from a different PostgreSQL-based product.

To perform a custom installation, complete the following steps:

1. Add the package repository required for your operating system. You can find the exact repositories and commands for each supported Linux distribution on the [Download page](#) for the selected Postgres Pro version.

2. **Choose Postgres Pro packages** required for your purposes and install them using the standard installation commands for your Linux distribution. The available packages are listed in Table 16.1.

   As a result, all files get installed into the `/opt/pgpro/std-14` directory.

3. Run `pg-wrapper` as root to make the installed client and server programs available via PATH and add SQL man pages to the man page configuration file. This utility is provided in the `postgrespro-std-14-client` package.

   `/opt/pgpro/std-14/bin/pg-wrapper links update`
For details on how to handle possible conflicts, see pg-wrapper description.

4. If you chose to install the postgrespro-std-14-server package, make sure to complete the following server setup:

a. Create the default database by running the helper script pg-setup as root with the initdb option:

```
/opt/pgpro/std-14/bin/pg-setup initdb [--tune=conf] [initdb_options]
```

where:

- the tune command-line argument sets the database configuration.
- initdb_options are regular initdb options.

**Note**

By default, pg-setup initializes the database cluster with checksums enabled. If this is not what you expect, specify the --no-data-checksums.

The pg-setup script performs database administration operations as user postgres. If you do not specify any initdb options, the default database is created in the /var/lib/pgpro/std-14/data directory, using localization settings specified in the LANG environment variable for the current session. All the LC_* environment variables are ignored.

Since the default database is created using the pg-setup script, the path to its data directory is stored in the /etc/default/postgrespro-std-14 file. All the subsequent pg-setup commands, as well as any commands that manage Postgres Pro service, affect this database only.

b. Start the server by running pg-setup as root, as follows:

```
/opt/pgpro/std-14/bin/pg-setup service start
```

Like vanilla PostgreSQL, Postgres Pro server runs on behalf of the postgres user.

**Note**

By default, automatic server startup is disabled, so you can manually control the database recovery after a system reboot. Optionally, you can configure the Postgres Pro server to start automatically. For details, see Section 16.1.3.2.

### 16.1.3.1. Choosing the Packages to Install

The table below lists all the available Postgres Pro Standard packages.

<table>
<thead>
<tr>
<th>Package</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>postgrespro-std-14</td>
<td>Top-level package that installs and configures Postgres Pro for server and client systems. Do not use this package for upgrades or migrations.</td>
</tr>
</tbody>
</table>

**Important**

Installing the postgrespro-std-14 package can delete existing installations of Postgres Pro and PostgreSQL-based products. Similarly, this Postgres Pro installation may...
### Binary Installation

<table>
<thead>
<tr>
<th>Package</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>postgrespro-std-14-client</td>
<td>Standard client applications, such as psql or pg_dump.</td>
</tr>
<tr>
<td>postgrespro-std-14-libs</td>
<td>Shared libraries required to deploy client applications, including libpq; runtime libraries for ECPG processor.</td>
</tr>
<tr>
<td>postgrespro-std-14-server</td>
<td>Postgres Pro server and PL/pgSQL server-side programming language.</td>
</tr>
<tr>
<td>postgrespro-std-14-contrib</td>
<td>Additional extensions and programs deployable on database servers.</td>
</tr>
<tr>
<td>postgrespro-std-14-devel</td>
<td>Header files and libraries for developing client applications and server extensions.</td>
</tr>
<tr>
<td></td>
<td>On Debian-based systems, this package is called postgrespro-std-14-dev.</td>
</tr>
<tr>
<td>postgrespro-std-14-plperl</td>
<td>Server-side programming language based on Perl.</td>
</tr>
<tr>
<td>postgrespro-std-14-plpython</td>
<td>Server-side programming language based on Python.</td>
</tr>
<tr>
<td>postgrespro-std-14-plpython3</td>
<td>Server-side programming language based on Python 3.</td>
</tr>
<tr>
<td></td>
<td>This package is unavailable on MSVSphere 6.3.</td>
</tr>
<tr>
<td>postgrespro-std-14-pltcl</td>
<td>Server-side programming language based on Tcl.</td>
</tr>
<tr>
<td>postgrespro-std-14-docs</td>
<td>Documentation (English).</td>

<tr>
<td>postgrespro-std-14-test</td>
<td>Test scripts for the server.</td>
</tr>
<tr>
<td></td>
<td>This package is only available on RHEL-based and SUSE systems.</td>
</tr>
<tr>
<td>postgrespro-std-14-jit</td>
<td>This package provides support for Just-in-Time (JIT) compilation.</td>
</tr>
<tr>
<td></td>
<td>This package is only available for the supported Debian and Ubuntu systems, Astra Linux Smolensk 1.6/1.7, Astra Linux Orel 2.12, ALT Linux 8/9/10, CentOS 7/8, SLES 15, OSnova 2.0, and RHEL 7/8.</td>
</tr>
<tr>
<td></td>
<td>To learn more about enabling and using JIT, see Chapter 30.</td>
</tr>
<tr>
<td>mamonsu</td>
<td>A monitoring agent for collecting Postgres Pro and system metrics.</td>
</tr>
<tr>
<td>pg-portal-modify-std-14</td>
<td>An extension to modify Postgres Pro cursors.</td>
</tr>
<tr>
<td>pg-probackup-std-14</td>
<td>pg_probackup utility.</td>
</tr>
<tr>
<td>pgpro-controldata</td>
<td>pgpro_controldata application to display control information of a PostgreSQL/Postgres Pro database cluster and compatibility information for a cluster and/or server.</td>
</tr>
</tbody>
</table>
 Besides, there are separate packages providing several external modules that have been pre-built for compatibility with Postgres Pro Standard:

**Table 16.2. Third-party Packages Built for Postgres Pro Standard**

<table>
<thead>
<tr>
<th>Package</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>orafce-std-14</td>
<td>This package implements in Postgres Pro some of the functions from the Oracle database that are missing (or behaving differently).</td>
</tr>
<tr>
<td>pg-filedump-std-14</td>
<td>A utility to format Postgres Pro heap/index/control files into a human-readable form.</td>
</tr>
<tr>
<td>pg-repack-std-14</td>
<td>Postgres Pro extension and utility for reorganizing tables.</td>
</tr>
<tr>
<td>pgbouncer</td>
<td>Connection pooler for Postgres Pro.</td>
</tr>
<tr>
<td>pgpro-pgbadger</td>
<td>Postgres Pro log analyzer that provides detailed reports and graphs.</td>
</tr>
<tr>
<td>pldebgger-std-14</td>
<td>A set of shared libraries that implement an API for debugging PL/pgSQL functions in Postgres Pro.</td>
</tr>
</tbody>
</table>

Additionally, Postgres Pro provides separate packages with debug information for some operating systems:

- On Debian-based systems, see the postgespro-std-14-dbg package.
- On RHEL-based systems, see the postgrespro-std-14-debuginfo package.
- On ALT Linux, all packages containing binary files have the corresponding -debuginfo packages.

Server installations require at least the following packages:

- postgrespro-std-14-server
- postgrespro-std-14-client
- postgrespro-std-14-libs

To use additional Postgres Pro extensions, you must also install the postgrespro-std-14-contrib package. On Debian-based systems, postgrespro-std-14-server package depends on postgrespro-std-14-contrib package, so the latter must always be installed together with the server.

For client installations, it is usually enough to install the postgrespro-std-14-client and postgrespro-std-14-libs packages. If you use custom applications and do not need standard client utilities such as psql, you can install the postgrespro-std-14-libs package only.

Development workstations require at least the following packages:

- postgrespro-std-14-libs
- postgrespro-std-14-devel/postgresql-std-14-dev

You may also want to install and configure the server with a test database on development systems. For details on additional configuration that may be required, Section 16.1.4.

**16.1.3.2. Enabling Automatic Server Startup**

If you are running a custom installation, automatic server startup is disabled by default. Once the default database is created, you can configure the server to start automatically upon system boot using service
management solutions available in your operating system or third-party high-availability software. To facilitate this task, postgrespro-std-14-server package provides the pg-setup script, which is installed in the /opt/pgpro/std-14/bin directory.

To enable server autostart, run the pg-setup script with the following options:

```
pg-setup service enable
```

If required, you can disable server autostart using the same script:

```
pg-setup service disable
```

Alternatively, you can use system service management solutions directly by running the autostart scripts for SysV-style init.d and systemd provided in the postgrespro-std-14-server package. Depending on your Linux distribution, Postgres Pro supports different service management solutions:

<table>
<thead>
<tr>
<th>Linux Distribution</th>
<th>Provided Scripts</th>
</tr>
</thead>
<tbody>
<tr>
<td>RHEL 7/8 and compatible distributions, SLES 12/15</td>
<td>systemd unit file</td>
</tr>
<tr>
<td>MSVSphere 6.3</td>
<td>SysV-style init.d script</td>
</tr>
<tr>
<td>Debian, Ubuntu, ALT Linux 8</td>
<td>Both systemd unit file and SysV-style init.d script</td>
</tr>
</tbody>
</table>

To use systemd for automatic server startup, run the following command:

```
systemctl enable postgrespro-std-14
```

To use SysV-style init.d script:

- On ALT Linux systems, run the following command:
  
  ```
systemctl enable postgrespro-std-14
  
  ```

- On Debian systems, use `update-rc.d`. See the corresponding man page for details.

### 16.1.4. Setting up Development Workstations

While installing postgrespro-std-14-libs and postgrespro-std-14-devel/postgrespro-std-14-dev packages may be enough, it is usually convenient to have the server set up on the development system. For quick setup, you can install postgrespro-std-14 package, which automatically configures the provided client and server programs and creates the default database. However, if you are going to use several PostgreSQL-based products simultaneously, follow the custom installation instructions in Section 16.1.3.

To compile programs with Postgres Pro libraries using the pg_config utility shipped with Postgres Pro, make sure it appears before the path to other pg_config versions, if any. Note that on RHEL-based systems pg_config is not added to `PATH` automatically. If you do not have any other pg_config versions on your system, you can use pg-wrapper provided in the postgrespro-std-14-client package to create a symbolic link to pg_config in the standard binary directory.

To compile programs using pkg-config command, add the `/opt/pgpro/std-14/lib/pkgconfig/` path to the `PKG_CONFIG_PATH` environment variable.

If you would like to compile Postgres Pro extensions that support JIT inlining, make sure to meet the following additional requirements:

- Install LLVM development package and Clang compiler. You must choose the packages of the same version that was used for the postgrespro-std-14-jit to be installed on the server. To determine the required version for the current Postgres Pro release, check the CLANG value in the `/opt/pgpro/std-14/lib/pgxs/src/Makefile.global` file.

- When running `make` or `make install` commands, specify the `with-llvm=yes` option to compile and install bitcode files for your extension. By default, bitcode compilation is disabled as it depends on Clang compiler availability.
16.1.4.1. Using Third-Party Programs with Postgres Pro

To use Postgres Pro server with a client program provided with a third-party product, you can install the version of PostgreSQL libraries that was used to compile this program. For example, if this program is provided with vanilla PostgreSQL, you may need to install the libpq or postgresql-libs packages available for your Linux distribution. In this case, the program may not be able to use some new features of Postgres Pro server, but it is probably not designed to use them anyway.

If you prefer to use Postgres Pro libraries with a third-party program, or would like to enable support for a new feature that does not require client application change, such as SCRAM authentication, you can recompile your program with Postgres Pro libraries.

Important

If the program is compiled with one version of libpq but used with another, its stable work cannot be guaranteed.

If you are creating .rpm or .deb packages for your program, it is recommended to do the following:

1. Add /opt/pgpro/std-14/bin to PATH inside your build scripts (.spec files or debian/rules).
2. Specify postgrespro-std-14-dev in the BuildDepends or BuildRequires tags for your program.

Thus, you can ensure that your package build process calls the right version of pg_config whenever the source package is rebuilt.

16.1.5. Configuring Multiple Postgres Pro Instances

To set up several Postgres Pro server instances with different data directories on Linux, do the following:

1. Install and configure Postgres Pro as explained in Section 16.1.2 or Section 16.1.3.
2. Once the first default database is created, run initdb specifying the path to a different data directory and any other parameters required to initialize another server instance.
3. Specify different ports for your server instances in the corresponding postgresql.conf files to avoid conflicts.
4. If required, configure automatic server startup, as follows:
   a. Create a copy of /etc/init.d/postgrespro-std-14 or /lib/systemd/system/postgrespro-std-14.service with a different name, specifying the path to the data directory.
   b. Enable automatic server startup using the provided autostart scripts for your system service management facility instead of pg-setup, as described in Section 16.1.3.2. Make sure to use the renamed copies of the scripts you created in step 1.

16.1.6. Antivirus Considerations

It is strongly recommended to avoid using antivirus software on systems where Postgres Pro is running because it may cause additional load on your environment and result in unexpected database behavior that would lead to performance and reliability issues. If you need to use antivirus software, make sure to exclude the following directories from virus scanning as they do not contain any executable files:

- PGDATA directory that stores main cluster data, usually located in /var/lib/pgpro/std-14/data unless you specified another directory in initdb options
- Paths to created tablespaces

16.2. Installing Postgres Pro Standard on Windows

Postgres Pro offers the following installation modes for the supported Windows systems:

- GUI installation using an interactive wizard
Binary Installation

- **Command-line installation**

Additionally, you have to set up the environment for using PL/Perl and PL/Python, if these procedural languages are required for your purposes. For details, see Section 16.2.4.

To avoid confusion, note that there are the following different users on Windows systems:

- Postgres Pro installation is performed on behalf of an operating system user. All the database files belong to this user.
- You must connect to the database cluster on behalf of the user created at installation time to be able to work with the database. This is not an operating system user.
- By default, Postgres Pro service is started on behalf of NT AUTHORITY\NetworkService, which is a special Windows Service Account. You can specify another Windows user for starting Postgres Pro service in the corresponding text box of the installer, if required. The provided user must have the right to start Windows services.

The minimum hardware required to install Postgres Pro, create a database cluster and start the database server are as follows:

- 1-GHz processor
- 1 GB of RAM
- 1 GB of disk space

Additional disk space is required for data or supporting components.

### 16.2.1. Supported Windows Versions

Postgres Pro is available for the following 64-bit Windows versions:

- Windows 10 or higher
- Windows Server 2012 R2 or higher

### 16.2.2. GUI Installation

Postgres Pro provides an installer with an interactive wizard that configures and installs Postgres Pro core components, creates the default database, and enables server autostart. The following components have their own installers that should be run separately once the core components are installed:

- `pg_probackup`

To install Postgres Pro core components, run the provided installer as administrator and follow the on-screen instructions. Make sure to take into account the following installation specifics:

- You can install all the Postgres Pro core components, or customize the installation by excluding server or developer components. Client utilities are always installed.
- The selected data directory must be empty. Otherwise, Postgres Pro cannot create the default database. The default data directory is `C:\Program Files\PostgresPro\14\data`.
- If the Allow external connections check box is selected (default), the installer modifies `postgresql.conf` and `pg_hba.conf` files to allow external connections. Otherwise, Postgres Pro server is listening for connections from the localhost only. If you decide to enable external connections when the installation is complete, you have to modify the Windows Firewall configuration to allow Postgres Pro server to accept connections.
- Make sure to remember the username and password you set up when installing Postgres Pro as it will be required to connect to the Postgres Pro server when using password-based authentication methods.
- By default, Postgres Pro uses `icu` collations. If you are upgrading an installation with the default collation provided by `libc`, such as PostgreSQL, make sure to choose `libc` collation provider in the corresponding drop-down list of the installer.
Binary Installation

- Postgres Pro provides a pre-configured psql that you can launch from the Start menu, so you do not have to configure the standard environment variables. However, if you would like to work with Postgres Pro from the standard command prompt without specifying full paths to the binary files, select the Set up environment variables check box.

Once the installation completes, your Postgres Pro instance is ready to use, with server autostart enabled. If you need more than one Postgres Pro instance on the same system, you have to configure them manually. For details, see Section 16.2.5.

16.2.3. Command-Line Installation

To install Postgres Pro from the command line, run the downloaded installer file passing one or more options described in Section 16.2.3.1.

16.2.3.1. Command-Line Options

Installation directory path:

/D=\path

Silent install:

/S

INI file that provides the options to customize the server installation:

/init=ini_file_name

If you would like to customize the installation, you must create the INI file manually, as described in Section 16.2.3.2.

16.2.3.2. INI File Format

You can add the following installation options to the [options] section of the INI file:

- **InstallDir** — path where to install server. If you specified the /D option on the command line, it will be overwritten by the InstallDir value.
- **DataDir** — path where to create default database
- **Port** — TCP/IP port to listen. Default: 5432.
- **SuperUser** — name of the database user who will have admin rights in the database
- **Password** — password of the user
- **noExtConnections = 1** — do not allow external connections
- **Coding = UNICODE** — character encoding to use in the database
- **Locale** — locale to use in the database. There can be several different locales for each encoding
- **vcredist = no** — do not install Visual C redistributable libraries (use it only if these libraries are already installed on your system)
- **envvar = 1** — set up environment variables helpful for Postgres Pro: PGDATA, PGDATABASE, PGUSER, PGPORT, PGLOCALEDIR
- **needoptimization = 0** — disable automatic tuning of configuration parameters based on the available system resources.
- **datachecksums = 0** — disable data checksums for the cluster.
- **serviceaccount** — specify a Windows user for starting Postgres Pro service. The provided user must have the right to start Windows services. By default, Postgres Pro service is started on behalf of NT AUTHORITY\NetworkService, which is a special Windows Service Account.
- **servicepassword** — provide the password for the Windows user specified in the serviceaccount option.
- **serviceid** — change Postgres Pro service name.
- **islibc = 1** — use libc as the provider of the default collation.

16.2.4. Loading Procedural Languages

Postgres Pro distribution for Windows systems includes PL/Perl and PL/Python procedural languages.
16.2.4.1. Setting up the Environment for PL/Python

To configure the system for using PL/Python, complete the following steps:

1. Download and install the latest available version of Python 2.7 for Windows. Choose the 64-bit version as Postgres Pro server has 64-bit architecture type. You can find the installers at https://www.python.org/.

2. Create the PL/Python extension by running the following command in psql:

   ```sql
   CREATE EXTENSION plpythonu
   ```

   **Tip**

   In some cases, when you create a PL/Python function, the connection to the server is lost and the server log shows the following error message:

   ```text
   ImportError: module site not found
   ```

   To avoid this issue, try to specify the Python installation directory in the `PYTHONHOME` environment variable and restart the Postgres Pro service.

16.2.4.2. Setting up the Environment for PL/Perl

To configure the system for using PL/Perl, complete the following steps:

2. Make sure to select the Add Perl to the PATH environment variable option in the installation wizard.

3. Restart the Postgres Pro server.

4. Create the PL/Perl extension by running the following command in psql:

   ```sql
   CREATE EXTENSION plperlu
   ```

16.2.5. Configuring Multiple Postgres Pro Instances

To set up several Postgres Pro server instances with different data directories on Windows, do the following:

1. Install Postgres Pro as explained in Section 16.2.2 or Section 16.2.3. The installed binary files are shared by all Postgres Pro instances, so you need to complete this step only once.

2. Select an empty folder that your new Postgres Pro instance will use as the data directory. For example, `C:\Program Files\PostgresPro\14\data2`. Make sure to grant Full Control permissions for this folder to the current OS user that will own the database files and the user on behalf of which the server is running (NT AUTHORITY\NetworkService by default).

3. Run `initdb` specifying the path to the new data directory and any other parameters required to initialize another server instance. For example:

   ```cmd
   "C:\Program Files\PostgresPro\14\bin\initdb.exe" --encoding=UTF8 -U "postgres" -D "C:\Program Files\PostgresPro\14\data2"
   ```

   Alternatively, you can stop the running server and copy the contents of the existing data directory into the newly created folder. In this case, the new Postgres Pro instance inherits all the settings of the original instance, including authentication settings.

4. Modify `postgresql.conf` settings for the new Postgres Pro instance as required. Make sure to specify different ports for your server instances to avoid conflicts.

5. Open the command prompt as Administrator and register a new Postgres Pro service with a unique name, for example, `postgrespro-data2`:

   ```cmd
   "C:\Program Files\PostgresPro\14\bin\pg_ctl.exe" register -N "postgrespro-data2" -U "NT AUTHORITY\NetworkService" -D "C:\Program Files\PostgresPro\14\data2" -W
   ```
Binary Installation

Start the registered service:

```bash
sc start "postgrespro-data2"
```

Once the service is started, your Postgres Pro instance is ready to use. If you need any additional Postgres Pro extensions, make sure to enable them for the new instance as explained in Section 16.3.

16.2.6. Uninstalling Postgres Pro Standard

The procedure of uninstalling Postgres Pro Standard depends on the number of Postgres Pro instances set up on your system.

If you have a single Postgres Pro instance created at installation time, you only need to run the `C:\Program Files\PostgresPro\14\uninstall.exe` program. This program automatically stops the server and unregisters the service for this instance.

If you have created any additional Postgres Pro instances, you have to complete the following steps:

1. Stop the server for each instance:

   ```bash
   "C:\Program Files\PostgresPro\14\bin\pg_ctl.exe" stop -D "C:\Program Files\PostgresPro\14\data_dir" -m fast -w
   ```

2. Unregister the service for each instance:

   ```bash
   "C:\Program Files\PostgresPro\14\bin\pg_ctl.exe" unregister -N "postgrespro_service_name"
   ```

3. Run the `C:\Program Files\PostgresPro\14\uninstall.exe` to uninstall Postgres Pro binary files.

16.2.7. Antivirus Considerations

It is strongly recommended to avoid using antivirus software on systems where Postgres Pro is running because it may cause additional load on your environment and result in unexpected database behavior that would lead to performance and reliability issues. If you need to use antivirus software, make sure to exclude the following directories from virus scanning as they do not contain any executable files:

- PGDATA directory that stores main cluster data, usually located in `C:\Program Files\PostgresPro\14\data` unless you specified another directory in initdb options
- Paths to created tablespaces

16.3. Installing Additional Supplied Modules

Postgres Pro comes with a set of additional server extensions, or modules. On Linux, these extensions are provided in the `postgrespro-contrib` package. On Windows, these extensions are installed together with the server components.

Once you have the binary files installed, you have to enable additional extensions in the database in order to use them. In most cases, you only need to issue the `CREATE EXTENSION` command. However, some extensions also require shared libraries to be preloaded on server startup. If you want to use such extensions, you need to configure parameter

```bash
shared_preload_libraries = 'lib1, lib2, lib3'
```

in the `postgresql.conf` file of your Postgres Pro database instance and restart the server before executing the `CREATE EXTENSION` statement.

For the exact installation and configuration instructions for each particular extension, see the corresponding documentation under Appendix F.

To get the list of extensions available in your Postgres Pro installation, you can view the `pg_available_extensions` system catalog.
16.4. Migrating to Postgres Pro

Different major versions of Postgres Pro, as well as different PostgreSQL-based products based on the same major version, can have binary incompatible databases, so you cannot replace the server binary and continue running. To convert databases that used previous major versions, you must perform a dump/restore using `pg_dumpall` or use the `pg_upgrade` utility.

For upgrade instructions specific to a particular release, see the Release Notes for the corresponding Postgres Pro version.
Chapter 17. Server Setup and Operation

This chapter discusses how to set up and run the database server, and its interactions with the operating system.

The directions in this chapter assume that you are working with plain PostgreSQL without any additional infrastructure, for example a copy that you built from source according to the directions in the preceding chapters. If you are working with a pre-packaged or vendor-supplied version of PostgreSQL, it is likely that the packager has made special provisions for installing and starting the database server according to your system's conventions. Consult the package-level documentation for details.

17.1. The Postgres Pro User Account

As with any server daemon that is accessible to the outside world, it is advisable to run Postgres Pro under a separate user account. This user account should only own the data that is managed by the server, and should not be shared with other daemons. (For example, using the user nobody is a bad idea.) In particular, it is advisable that this user account not own the Postgres Pro executable files, to ensure that a compromised server process could not modify those executables.

Pre-packaged versions of PostgreSQL will typically create a suitable user account automatically during package installation.

To add a Unix user account to your system, look for a command useradd or adduser. The user name postgres is often used, and is assumed throughout this book, but you can use another name if you like.

17.2. Creating a Database Cluster

Before you can do anything, you must initialize a database storage area on disk. We call this a database cluster. (The SQL standard uses the term catalog cluster.) A database cluster is a collection of databases that is managed by a single instance of a running database server. After initialization, a database cluster will contain a database named postgres, which is meant as a default database for use by utilities, users and third party applications. The database server itself does not require the postgres database to exist, but many external utility programs assume it exists. Another database created within each cluster during initialization is called template1. As the name suggests, this will be used as a template for subsequently created databases; it should not be used for actual work. (See Chapter 21 for information about creating new databases within a cluster.)

In file system terms, a database cluster is a single directory under which all data will be stored. We call this the data directory or data area. It is completely up to you where you choose to store your data. There is no default, although locations such as /usr/local/pgsql/data or /var/lib/pgsql/data are popular. The data directory must be initialized before being used, using the program initdb which is installed with Postgres Pro.

If you are using a pre-packaged version of PostgreSQL, it may well have a specific convention for where to place the data directory, and it may also provide a script for creating the data directory. In that case you should use that script in preference to running initdb directly. Consult the package-level documentation for details.

To initialize a database cluster manually, run initdb and specify the desired file system location of the database cluster with the -D option, for example:

$ initdb -D /usr/local/pgsql/data

Note that you must execute this command while logged into the Postgres Pro user account, which is described in the previous section.

Tip

As an alternative to the -D option, you can set the environment variable PGDATA.
Alternatively, you can run initdb via the pg_ctl program like so:

```
$ pg_ctl -D /usr/local/pgsql/data initdb
```

This may be more intuitive if you are using pg_ctl for starting and stopping the server (see Section 17.3), so that pg_ctl would be the sole command you use for managing the database server instance.

initdb will attempt to create the directory you specify if it does not already exist. Of course, this will fail if initdb does not have permissions to write in the parent directory. It's generally recommendable that the Postgres Pro user own not just the data directory but its parent directory as well, so that this should not be a problem. If the desired parent directory doesn't exist either, you will need to create it first, using root privileges if the grandparent directory isn't writable. So the process might look like this:

```
root# mkdir /usr/local/pgsql
root# chown postgres /usr/local/pgsql
root# su postgres
postgres$ initdb -D /usr/local/pgsql/data
```

initdb will refuse to run if the data directory exists and already contains files; this is to prevent accidentally overwriting an existing installation.

Because the data directory contains all the data stored in the database, it is essential that it be secured from unauthorized access. initdb therefore revokes access permissions from everyone but the Postgres Pro user, and optionally, group. Group access, when enabled, is read-only. This allows an unprivileged user in the same group as the cluster owner to take a backup of the cluster data or perform other operations that only require read access.

Note that enabling or disabling group access on an existing cluster requires the cluster to be shut down and the appropriate mode to be set on all directories and files before restarting Postgres Pro. Otherwise, a mix of modes might exist in the data directory. For clusters that allow access only by the owner, the appropriate modes are 0700 for directories and 0600 for files. For clusters that also allow reads by the group, the appropriate modes are 0750 for directories and 0640 for files.

However, while the directory contents are secure, the default client authentication setup allows any local user to connect to the database and even become the database superuser. If you do not trust other local users, we recommend you use one of initdb's -W, --pwprompt or --pwfile options to assign a password to the database superuser. Also, specify -A md5 or -A password so that the default trust authentication mode is not used; or modify the generated pg_hba.conf file after running initdb, but before you start the server for the first time. (Other reasonable approaches include using peer authentication or file system permissions to restrict connections. See Chapter 19 for more information.)

initdb also initializes the default locale for the database cluster. Normally, it will just take the locale settings in the environment and apply them to the initialized database. It is possible to specify a different locale for the database; more information about that can be found in Section 22.1. The default sort order used within the particular database cluster is set by initdb, and while you can create new databases using different sort order, the order used in the template databases that initdb creates cannot be changed without dropping and recreating them. There is also a performance impact for using locales other than C or POSIX. Therefore, it is important to make this choice correctly the first time.

initdb also sets the default character set encoding for the database cluster. Normally this should be chosen to match the locale setting. For details see Section 22.3.

Non-C and non-POSIX locales rely on the operating system's collation library for character set ordering. This controls the ordering of keys stored in indexes. For this reason, a cluster cannot switch to an incompatible collation library version, either through snapshot restore, binary streaming replication, a different operating system, or an operating system upgrade.

17.2.1. Use of Secondary File Systems

Many installations create their database clusters on file systems (volumes) other than the machine's "root" volume. If you choose to do this, it is not advisable to try to use the secondary volume's topmost
directory (mount point) as the data directory. Best practice is to create a directory within the mount-point directory that is owned by the Postgres Pro user, and then create the data directory within that. This avoids permissions problems, particularly for operations such as pg_upgrade, and it also ensures clean failures if the secondary volume is taken offline.

17.2.2. File Systems

Generally, any file system with POSIX semantics can be used for Postgres Pro. Users prefer different file systems for a variety of reasons, including vendor support, performance, and familiarity. Experience suggests that, all other things being equal, one should not expect major performance or behavior changes merely from switching file systems or making minor file system configuration changes.

17.2.2.1. NFS

It is possible to use an NFS file system for storing the Postgres Pro data directory. Postgres Pro does nothing special for NFS file systems, meaning it assumes NFS behaves exactly like locally-connected drives. Postgres Pro does not use any functionality that is known to have nonstandard behavior on NFS, such as file locking.

The only firm requirement for using NFS with Postgres Pro is that the file system is mounted using the hard option. With the hard option, processes can “hang” indefinitely if there are network problems, so this configuration will require a careful monitoring setup. The soft option will interrupt system calls in case of network problems, but Postgres Pro will not repeat system calls interrupted in this way, so any such interruption will result in an I/O error being reported.

It is not necessary to use the sync mount option. The behavior of the async option is sufficient, since Postgres Pro issues fsync calls at appropriate times to flush the write caches. (This is analogous to how it works on a local file system.) However, it is strongly recommended to use the sync export option on the NFS server on systems where it exists (mainly Linux). Otherwise, an fsync or equivalent on the NFS client is not actually guaranteed to reach permanent storage on the server, which could cause corruption similar to running with the parameter fsync off. The defaults of these mount and export options differ between vendors and versions, so it is recommended to check and perhaps specify them explicitly in any case to avoid any ambiguity.

In some cases, an external storage product can be accessed either via NFS or a lower-level protocol such as iSCSI. In the latter case, the storage appears as a block device and any available file system can be created on it. That approach might relieve the DBA from having to deal with some of the idiosyncrasies of NFS, but of course the complexity of managing remote storage then happens at other levels.

17.3. Starting the Database Server

Important

In binary installations on Linux systems, the default database is located in /var/lib/pgpro/std-14/data, unless you specify a custom directory. See Section 16.1 for details.

Before anyone can access the database, you must start the database server. The database server program is called postgres.

If you are using a pre-packaged version of PostgreSQL, it almost certainly includes provisions for running the server as a background task according to the conventions of your operating system. Using the package’s infrastructure to start the server will be much less work than figuring out how to do this yourself. Consult the package-level documentation for details.

The bare-bones way to start the server manually is just to invoke postgres directly, specifying the location of the data directory with the -D option, for example:

$ postgres -D /usr/local/pgsql/data
which will leave the server running in the foreground. This must be done while logged into the Postgres Pro user account. Without `-D`, the server will try to use the data directory named by the environment variable `PGDATA`. If that variable is not provided either, it will fail.

Normally it is better to start `postgres` in the background. For this, use the usual Unix shell syntax:

```bash
$ postgres -D /usr/local/pgsql/data >logfile 2>&1 &
```

It is important to store the server's stdout and stderr output somewhere, as shown above. It will help for auditing purposes and to diagnose problems. (See Section 23.3 for a more thorough discussion of log file handling.)

The `postgres` program also takes a number of other command-line options. For more information, see the `postgres` reference page and Chapter 18 below.

This shell syntax can get tedious quickly. Therefore the wrapper program `pg_ctl` is provided to simplify some tasks. For example:

```bash
pg_ctl start -l logfile
```

will start the server in the background and put the output into the named log file. The `-D` option has the same meaning here as for `postgres`. `pg_ctl` is also capable of stopping the server.

Normally, you will want to start the database server when the computer boots. Autostart scripts are operating-system-specific. There are a few example scripts distributed with Postgres Pro in the `contrib/start-scripts` directory. Installing one will require root privileges.

Different systems have different conventions for starting up daemons at boot time. Many systems have a file `/etc/rc.local` or `/etc/rc.d/rc.local`. Others use `init.d` or `rc.d` directories. Whatever you do, the server must be run by the Postgres Pro user account and not by `root` or any other user. Therefore you probably should form your commands using `su postgres -c '...'. For example:

```bash
su postgres -c 'pg_ctl start -D /usr/local/pgsql/data -l serverlog'
```

Here are a few more operating-system-specific suggestions. (In each case be sure to use the proper installation directory and user name where we show generic values.)

- For FreeBSD, look at the file `contrib/start-scripts/freebsd` in the Postgres Pro source distribution.
- On OpenBSD, add the following lines to the file `/etc/rc.local`:

  ```bash
  if [ -x /usr/local/pgsql/bin/pg_ctl -a -x /usr/local/pgsql/bin/postgres ]; then
    su -l postgres -c '/usr/local/pgsql/bin/pg_ctl start -s -l /var/postgresql/log -D /usr/local/pgsql/data'
    echo -n ' postgresql
  fi
  ```

- On Linux systems either add

  ```bash
  /usr/local/pgsql/bin/pg_ctl start -l logfile -D /usr/local/pgsql/data
  ```

  to `/etc/rc.d/rc.local` or `/etc/rc.local` or look at the file `contrib/start-scripts/linux` in the Postgres Pro source distribution.

When using systemd, you can use the following service unit file (e.g., at `/etc/systemd/system/postgresql.service`):

```ini
[Unit]
Description=Postgres Pro database server
Documentation=man:postgres(1)

[Service]
Type=notify
User=postgres
```
Server Setup and Operation

ExecStart=/usr/local/pgsql/bin/postgres -D /usr/local/pgsql/data
ExecReload=/bin/kill -HUP $MAINPID
KillMode=mixed
KillSignal=SIGINT
TimeoutSec=0

[Install]
WantedBy=multi-user.target

Using Type=notify requires that the server binary was built with configure --with-systemd.

Consider carefully the timeout setting. systemd has a default timeout of 90 seconds as of this writing and will kill a process that does not notify readiness within that time. But a Postgres Pro server that might have to perform crash recovery at startup could take much longer to become ready. The suggested value of 0 disables the timeout logic.

- On NetBSD, use either the FreeBSD or Linux start scripts, depending on preference.
- On Solaris, create a file called /etc/init.d/postgresql that contains the following line:

  su - postgres -c "/usr/local/pgsql/bin/pg_ctl start -l logfile -D /usr/local/pgsql/data"

  Then, create a symbolic link to it in /etc/rc3.d as S99postgresql.

While the server is running, its PID is stored in the file postmaster.pid in the data directory. This is used to prevent multiple server instances from running in the same data directory and can also be used for shutting down the server.

17.3.1. Server Start-up Failures

There are several common reasons the server might fail to start. Check the server’s log file, or start it by hand (without redirecting standard output or standard error) and see what error messages appear. Below we explain some of the most common error messages in more detail.

LOG: could not bind IPv4 address "127.0.0.1": Address already in use
HINT: Is another postmaster already running on port 5432? If not, wait a few seconds and retry.
FATAL: could not create any TCP/IP sockets

This usually means just what it suggests: you tried to start another server on the same port where one is already running. However, if the kernel error message is not Address already in use or some variant of that, there might be a different problem. For example, trying to start a server on a reserved port number might draw something like:

$ postgres -p 666
LOG: could not bind IPv4 address "127.0.0.1": Permission denied
HINT: Is another postmaster already running on port 666? If not, wait a few seconds and retry.
FATAL: could not create any TCP/IP sockets

A message like:

FATAL: could not create shared memory segment: Invalid argument
DETAIL: Failed system call was shmget(key=5440001, size=4011376640, 03600).

probably means your kernel's limit on the size of shared memory is smaller than the work area Postgres Pro is trying to create (4011376640 bytes in this example). This is only likely to happen if you have set shared_memory_type to sysv. In that case, you can try starting the server with a smaller-than-normal number of buffers (shared_buffers), or reconfigure your kernel to increase the allowed shared memory size. You might also see this message when trying to start multiple servers on the same machine, if their total space requested exceeds the kernel limit.

An error like:
Server Setup and Operation

FATAL: could not create semaphores: No space left on device
DETAIL: Failed system call was semget(5440126, 17, 03600).

does not mean you've run out of disk space. It means your kernel's limit on the number of System V semaphores is smaller than the number Postgres Pro wants to create. As above, you might be able to work around the problem by starting the server with a reduced number of allowed connections (max_connections), but you'll eventually want to increase the kernel limit.

Details about configuring System V IPC facilities are given in Section 17.4.1.

17.3.2. Client Connection Problems

Although the error conditions possible on the client side are quite varied and application-dependent, a few of them might be directly related to how the server was started. Conditions other than those shown below should be documented with the respective client application.

psql: error: connection to server at "server.joe.com" (123.123.123.123), port 5432 failed: Connection refused

Is the server running on that host and accepting TCP/IP connections?

This is the generic "I couldn't find a server to talk to" failure. It looks like the above when TCP/IP communication is attempted. A common mistake is to forget to configure the server to allow TCP/IP connections.

Alternatively, you might get this when attempting Unix-domain socket communication to a local server:

psql: error: connection to server on socket "/tmp/.s.PGSQL.5432" failed: No such file or directory

Is the server running locally and accepting connections on that socket?

If the server is indeed running, check that the client's idea of the socket path (here /tmp) agrees with the server's unix_socket_directories setting.

A connection failure message always shows the server address or socket path name, which is useful in verifying that the client is trying to connect to the right place. If there is in fact no server listening there, the kernel error message will typically be either Connection refused or No such file or directory, as illustrated. (It is important to realize that Connection refused in this context does not mean that the server got your connection request and rejected it. That case will produce a different message, as shown in Section 19.15.) Other error messages such as Connection timed out might indicate more fundamental problems, like lack of network connectivity, or a firewall blocking the connection.

17.4. Managing Kernel Resources

Postgres Pro can sometimes exhaust various operating system resource limits, especially when multiple copies of the server are running on the same system, or in very large installations. This section explains the kernel resources used by Postgres Pro and the steps you can take to resolve problems related to kernel resource consumption.

17.4.1. Shared Memory and Semaphores

Postgres Pro requires the operating system to provide inter-process communication (IPC) features, specifically shared memory and semaphores. Unix-derived systems typically provide "System V" IPC, "POSIX" IPC, or both. Windows has its own implementation of these features and is not discussed here.

By default, Postgres Pro allocates a very small amount of System V shared memory, as well as a much larger amount of anonymous mmap shared memory. Alternatively, a single large System V shared memory region can be used (see shared_memory_type). In addition a significant number of semaphores, which can be either System V or POSIX style, are created at server startup. Currently, POSIX semaphores are used on Linux and FreeBSD systems while other platforms use System V semaphores.

System V IPC features are typically constrained by system-wide allocation limits. When Postgres Pro exceeds one of these limits, the server will refuse to start and should leave an instructive error message.
Server Setup and Operation

describing the problem and what to do about it. (See also Section 17.3.1.) The relevant kernel parameters are named consistently across different systems; Table 17.1 gives an overview. The methods to set them, however, vary. Suggestions for some platforms are given below.

Table 17.1. System V IPC Parameters

<table>
<thead>
<tr>
<th>Name</th>
<th>Description</th>
<th>Values needed to run one Postgres Pro instance</th>
</tr>
</thead>
<tbody>
<tr>
<td>SHMMAX</td>
<td>Maximum size of shared memory segment (bytes)</td>
<td>at least 1kB, but the default is usually much higher</td>
</tr>
<tr>
<td>SHMMIN</td>
<td>Minimum size of shared memory segment (bytes)</td>
<td>1</td>
</tr>
<tr>
<td>SHMALL</td>
<td>Total amount of shared memory available (bytes or pages)</td>
<td>same as SHMMAX if bytes, or ceil(SHMMAX/PAGE_SIZE) if pages, plus room for other applications</td>
</tr>
<tr>
<td>SHMSEG</td>
<td>Maximum number of shared memory segments per process</td>
<td>only 1 segment is needed, but the default is much higher</td>
</tr>
<tr>
<td>SHMMNI</td>
<td>Maximum number of shared memory segments system-wide</td>
<td>like SHMSEG plus room for other applications</td>
</tr>
<tr>
<td>SEMMNI</td>
<td>Maximum number of semaphore identifiers (i.e., sets)</td>
<td>at least ceil((max_connections + autovacuum_max_workers + max_wal_senders + max_worker_processes + 5) / 16) plus room for other applications</td>
</tr>
<tr>
<td>SEMMNS</td>
<td>Maximum number of semaphores system-wide</td>
<td>ceil((max_connections + autovacuum_max_workers + max_wal_senders + max_worker_processes + 5) / 16) * 17 plus room for other applications</td>
</tr>
<tr>
<td>SEMMSL</td>
<td>Maximum number of semaphores per set</td>
<td>at least 17</td>
</tr>
<tr>
<td>SEMMAP</td>
<td>Number of entries in semaphore map</td>
<td>see text</td>
</tr>
<tr>
<td>SEMVMX</td>
<td>Maximum value of semaphore</td>
<td>at least 1000 (The default is often 32767; do not change unless necessary)</td>
</tr>
</tbody>
</table>

Postgres Pro requires a few bytes of System V shared memory (typically 48 bytes, on 64-bit platforms) for each copy of the server. On most modern operating systems, this amount can easily be allocated. However, if you are running many copies of the server or you explicitly configure the server to use large amounts of System V shared memory (see shared_memory_type and dynamic_shared_memory_type), it may be necessary to increase SHMALL, which is the total amount of System V shared memory system-wide. Note that SHMALL is measured in pages rather than bytes on many systems.

Less likely to cause problems is the minimum size for shared memory segments (SHMMIN), which should be at most approximately 32 bytes for Postgres Pro (it is usually just 1). The maximum number of segments system-wide (SHMMNI) or per-process (SHMSEG) are unlikely to cause a problem unless your system has them set to zero.

When using System V semaphores, Postgres Pro uses one semaphore per allowed connection (max_connections), allowed autovacuum worker process (autovacuum_max_workers) and allowed background process (max_worker_processes), in sets of 16. Each such set will also contain a 17th semaphore which contains a “magic number”, to detect collision with semaphore sets used by other applications. The maximum number of semaphores in the system is set by SEMMNS, which consequently must be at least as high as max_connections + autovacuum_max_workers + max_wal_senders + max_worker_processes, plus max_worker_processes, plus one extra for each 16 allowed connections plus workers (see the formula in Table 17.1). The parameter SEMMNI determines the limit on the number of semaphore sets that can exist on the system at one time. Hence this parameter must be at least ceil((max_connections + autovacuum_max_workers + max_wal_senders + max_worker_processes + 5) / 16). Lowering the
number of allowed connections is a temporary workaround for failures, which are usually confusingly worded “No space left on device”, from the function `semget`.

In some cases it might also be necessary to increase `SEMMAP` to be at least on the order of `SEMMNS`. If the system has this parameter (many do not), it defines the size of the semaphore resource map, in which each contiguous block of available semaphores needs an entry. When a semaphore set is freed it is either added to an existing entry that is adjacent to the freed block or it is registered under a new map entry. If the map is full, the freed semaphores get lost (until reboot). Fragmentation of the semaphore space could over time lead to fewer available semaphores than there should be.

Various other settings related to “semaphore undo”, such as `SEMNU` and `SEMUME`, do not affect Postgres Pro.

When using POSIX semaphores, the number of semaphores needed is the same as for System V, that is one semaphore per allowed connection (`max_connections`), allowed autovacuum worker process (`autovacuum_max_workers`) and allowed background process (`max_worker_processes`). On the platforms where this option is preferred, there is no specific kernel limit on the number of POSIX semaphores.

AIX

It should not be necessary to do any special configuration for such parameters as `SHMMAX`, as it appears this is configured to allow all memory to be used as shared memory. That is the sort of configuration commonly used for other databases such as DB/2.

It might, however, be necessary to modify the global `ulimit` information in `/etc/security/limits`, as the default hard limits for file sizes (`fsize`) and numbers of files (`nofiles`) might be too low.

FreeBSD

The default shared memory settings are usually good enough, unless you have set `shared_memory_type` to `sysv`. System V semaphores are not used on this platform.

The default IPC settings can be changed using the `sysctl` or `loader` interfaces. The following parameters can be set using `sysctl`:

```bash
# sysctl kern.ipc.shmall=32768
# sysctl kern.ipc.shmmax=134217728
```

To make these settings persist over reboots, modify `/etc/sysctl.conf`.

If you have set `shared_memory_type` to `sysv`, you might also want to configure your kernel to lock System V shared memory into RAM and prevent it from being paged out to swap. This can be accomplished using the `sysctl` setting `kern.ipc.shm_use_phys`.

If running in a FreeBSD jail, you should set its `sysvshm` parameter to `new`, so that it has its own separate System V shared memory namespace. (Before FreeBSD 11.0, it was necessary to enable shared access to the host’s IPC namespace from jails, and take measures to avoid collisions.)

NetBSD

The default shared memory settings are usually good enough, unless you have set `shared_memory_type` to `sysv`. You will usually want to increase `kern.ipc.semmni` and `kern.ipc.semmns`, as NetBSD’s default settings for these are uncomfortably small.

IPC parameters can be adjusted using `sysctl`, for example:

```bash
# sysctl -w kern.ipc.semmni=100
```

To make these settings persist over reboots, modify `/etc/sysctl.conf`.

If you have set `shared_memory_type` to `sysv`, you might also want to configure your kernel to lock System V shared memory into RAM and prevent it from being paged out to swap. This can be accomplished using the `sysctl` setting `kern.ipc.shm_use_phys`. 

470
OpenBSD

The default shared memory settings are usually good enough, unless you have set `shared_memory_type` to `sysv`. You will usually want to increase `kern.seminfo.semmni` and `kern.seminfo.semmns`, as OpenBSD’s default settings for these are uncomfortably small.

IPC parameters can be adjusted using `sysctl`, for example:

```
# sysctl kern.seminfo.semmni=100
```

To make these settings persist over reboots, modify `/etc/sysctl.conf`.

HP-UX

The default settings tend to suffice for normal installations.

IPC parameters can be set in the System Administration Manager (SAM) under Kernel Configuration → Configurable Parameters. Choose Create A New Kernel when you’re done.

Linux

The default shared memory settings are usually good enough, unless you have set `shared_memory_type` to `sysv`, and even then only on older kernel versions that shipped with low defaults. System V semaphores are not used on this platform.

The shared memory size settings can be changed via the `sysctl` interface. For example, to allow 16 GB:

```
$ sysctl -w kernel.shmmax=17179869184
$ sysctl -w kernel.shmall=4194304
```

To make these settings persist over reboots, see `/etc/sysctl.conf`.

macOS

The default shared memory and semaphore settings are usually good enough, unless you have set `shared_memory_type` to `sysv`.

The recommended method for configuring shared memory in macOS is to create a file named `/etc/sysctl.conf`, containing variable assignments such as:

```
kern.sysv.shmmax=4194304
kern.sysv.shmmin=1
kern.sysv.shmmni=32
kern.sysv.shmseg=8
kern.sysv.shmall=1024
```

Note that in some macOS versions, all five shared-memory parameters must be set in `/etc/sysctl.conf`, else the values will be ignored.

`SHMMAX` can only be set to a multiple of 4096.

`SHMALL` is measured in 4 kB pages on this platform.

It is possible to change all but `SHMMNI` on the fly, using `sysctl`. But it’s still best to set up your preferred values via `/etc/sysctl.conf`, so that the values will be kept across reboots.

Solaris illumos

The default shared memory and semaphore settings are usually good enough for most Postgres Pro applications. Solaris defaults to a `SHMMAX` of one-quarter of system RAM. To further adjust this setting, use a project setting associated with the `postgres` user. For example, run the following as `root`:

```
projadd -c "Postgres Pro DB User" -K "project.max-shm-memory=(privileged,8GB,deny)" -U postgres -G postgres user.postgres
```
This command adds the user.postgres project and sets the shared memory maximum for the postgres user to 8GB, and takes effect the next time that user logs in, or when you restart Postgres Pro (not reload). The above assumes that Postgres Pro is run by the postgres user in the postgres group. No server reboot is required.

Other recommended kernel setting changes for database servers which will have a large number of connections are:

- `project.max-shm-ids=(priv,32768,deny)`
- `project.max-sem-ids=(priv,4096,deny)`
- `project.max-msg-ids=(priv,4096,deny)`

Additionally, if you are running Postgres Pro inside a zone, you may need to raise the zone resource usage limits as well. See "Chapter2: Projects and Tasks" in the `System Administrator's Guide` for more information on `projects` and `prctl`.

### 17.4.2. systemd RemoveIPC

If systemd is in use, some care must be taken that IPC resources (including shared memory) are not prematurely removed by the operating system. This is especially of concern when installing Postgres Pro from source. Users of distribution packages of Postgres Pro are less likely to be affected, as the postgres user is then normally created as a system user.

The setting `RemoveIPC` in `logind.conf` controls whether IPC objects are removed when a user fully logs out. System users are exempt. This setting defaults to on in stock systemd, but some operating system distributions default it to off.

A typical observed effect when this setting is on is that shared memory objects used for parallel query execution are removed at apparently random times, leading to errors and warnings while attempting to open and remove them, like:

```
WARNING: could not remove shared memory segment "'/PostgreSQL.1450751626'": No such file or directory
```

Different types of IPC objects (shared memory vs. semaphores, System V vs. POSIX) are treated slightly differently by systemd, so one might observe that some IPC resources are not removed in the same way as others. But it is not advisable to rely on these subtle differences.

A “user logging out” might happen as part of a maintenance job or manually when an administrator logs in as the postgres user or something similar, so it is hard to prevent in general.

What is a “system user” is determined at systemd compile time from the `SYS_UID_MAX` setting in `/etc/login.defs`.

Packaging and deployment scripts should be careful to create the postgres user as a system user by using `useradd -r, adduser --system`, or equivalent.

Alternatively, if the user account was created incorrectly or cannot be changed, it is recommended to set `RemoveIPC=no` in `/etc/systemd/logind.conf` or another appropriate configuration file.

Caution

At least one of these two things has to be ensured, or the Postgres Pro server will be very unreliable.

### 17.4.3. Resource Limits

Unix-like operating systems enforce various kinds of resource limits that might interfere with the operation of your Postgres Pro server. Of particular importance are limits on the number of processes...
Server Setup and Operation

per user, the number of open files per process, and the amount of memory available to each process. Each of these have a “hard” and a “soft” limit. The soft limit is what actually counts but it can be changed by the user up to the hard limit. The hard limit can only be changed by the root user. The system call setrlimit is responsible for setting these parameters. The shell's built-in command ulimit (Bourne shells) or limit (csh) is used to control the resource limits from the command line. On BSD-derived systems the file /etc/login.conf controls the various resource limits set during login. See the operating system documentation for details. The relevant parameters are maxproc, openfiles, and datasize. For example:

```
default:\n...:
datasize-cur=256M:\n:maxproc-cur=256:\n:openfiles-cur=256:\n...
```

(-cur is the soft limit. Append -max to set the hard limit.)

Kernels can also have system-wide limits on some resources.

- On Linux /proc/sys/fs/file-max determines the maximum number of open files that the kernel will support. It can be changed by writing a different number into the file or by adding an assignment in /etc/sysctl.conf. The maximum limit of files per process is fixed at the time the kernel is compiled; see /usr/src/linux/Documentation/proc.txt for more information.

The Postgres Pro server uses one process per connection so you should provide for at least as many processes as allowed connections, in addition to what you need for the rest of your system. This is usually not a problem but if you run several processes on one machine things might get tight.

The factory default limit on open files is often set to “socially friendly” values that allow many users to coexist on a machine without using an inappropriate fraction of the system resources. If you run many servers on a machine this is perhaps what you want, but on dedicated servers you might want to raise this limit.

On the other side of the coin, some systems allow individual processes to open large numbers of files; if more than a few processes do so then the system-wide limit can easily be exceeded. If you find this happening, and you do not want to alter the system-wide limit, you can set Postgres Pro's max_files_per_process configuration parameter to limit the consumption of open files.

17.4.4. Linux Memory Overcommit

The default virtual memory behavior on Linux is not optimal for Postgres Pro. Because of the way that the kernel implements memory overcommit, the kernel might terminate the Postgres Pro postmaster (the supervisor server process) if the memory demands of either Postgres Pro or another process cause the system to run out of virtual memory.

If this happens, you will see a kernel message that looks like this (consult your system documentation and configuration on where to look for such a message):

```
Out of Memory: Killed process 12345 (postgres).
```

This indicates that the postgres process has been terminated due to memory pressure. Although existing database connections will continue to function normally, no new connections will be accepted. To recover, Postgres Pro will need to be restarted.

One way to avoid this problem is to run Postgres Pro on a machine where you can be sure that other processes will not run the machine out of memory. If memory is tight, increasing the swap space of the operating system can help avoid the problem, because the out-of-memory (OOM) killer is invoked only when physical memory and swap space are exhausted.

If Postgres Pro itself is the cause of the system running out of memory, you can avoid the problem by changing your configuration. In some cases, it may help to lower memory-related configuration
parameters, particularly shared_buffers, work_mem, and hash_mem_multiplier. In other cases, the problem may be caused by allowing too many connections to the database server itself. In many cases, it may be better to reduce max_connections and instead make use of external connection-pooling software.

It is possible to modify the kernel's behavior so that it will not “overcommit” memory. Although this setting will not prevent the OOM killer from being invoked altogether, it will lower the chances significantly and will therefore lead to more robust system behavior. This is done by selecting strict overcommit mode via sysctl:

sysctl -w vm.overcommit_memory=2

or placing an equivalent entry in /etc/sysctl.conf. You might also wish to modify the related setting vm.overcommit_ratio. For details see the kernel documentation file https://www.kernel.org/doc/Documentation/vm/overcommit-accounting.

Another approach, which can be used with or without altering vm.overcommit_memory, is to set the process-specific OOM score adjustment value for the postmaster process to -1000, thereby guaranteeing it will not be targeted by the OOM killer. The simplest way to do this is to execute

echo -1000 > /proc/self/oom_score_adj

in the postmaster's startup script just before invoking the postmaster. Note that this action must be done as root, or it will have no effect; so a root-owned startup script is the easiest place to do it. If you do this, you should also set these environment variables in the startup script before invoking the postmaster:

export PG_OOM_ADJUST_FILE=/proc/self/oom_score_adj
export PG_OOM_ADJUST_VALUE=0

These settings will cause postmaster child processes to run with the normal OOM score adjustment of zero, so that the OOM killer can still target them at need. You could use some other value for PG_OOM_ADJUST_VALUE if you want the child processes to run with some other OOM score adjustment. (PG_OOM_ADJUST_VALUE can also be omitted, in which case it defaults to zero.) If you do not set PG_OOM_ADJUST_FILE, the child processes will run with the same OOM score adjustment as the postmaster, which is unwise since the whole point is to ensure that the postmaster has a preferential setting.

17.4.5. Linux Huge Pages

Using huge pages reduces overhead when using large contiguous chunks of memory, as Postgres Pro does, particularly when using large values of shared_buffers. To use this feature in Postgres Pro you need a kernel with CONFIG_HUGETLBFS=y and CONFIG_HUGETLB_PAGE=y. You will also have to configure the operating system to provide enough huge pages of the desired size. To estimate the number of huge pages needed, start Postgres Pro without huge pages enabled and check the postmaster's anonymous shared memory segment size, as well as the system's default and supported huge page sizes, using the /proc and /sys file systems. This might look like:

$ head -1 $PGDATA/postmaster.pid
4170

$ pmap 4170 | awk '/rw-s/ && /zero/ {print $2}'
6490428K

$ grep ^Hugepagesize /proc/meminfo
Hugepagesize: 2048 kB

$ ls /sys/kernel/mm/hugepages
hugepages-1048576kB hugepages-2048kB

In this example the default is 2MB, but you can also explicitly request either 2MB or 1GB with huge page size. Assuming 2MB huge pages, 6490428 / 2048 gives approximately 3169.154, so in this example we need at least 3170 huge pages. A larger setting would be appropriate if other programs on the machine also need huge pages. We can set this with:

# sysctl -w vm.nr_hugepages=3170

Don't forget to add this setting to /etc/sysctl.conf so that it is reapplied after reboots. For non-default huge page sizes, we can instead use:
echo 3170 > /sys/kernel/mm/hugepages/hugepages-2048kB/nr_hugepages

It is also possible to provide these settings at boot time using kernel parameters such as hugepagesz=2M
hugepages=3170.

Sometimes the kernel is not able to allocate the desired number of huge pages immediately due to fragmentation, so it might be necessary to repeat the command or to reboot. (Immediately after a reboot, most of the machine's memory should be available to convert into huge pages.) To verify the huge page allocation situation for a given size, use:

$ cat /sys/kernel/mm/hugepages/hugepages-2048kB/nr_hugepages

It may also be necessary to give the database server's operating system user permission to use huge pages by setting `vm.hugetlb_shm_group` via `sysctl`, and/or give permission to lock memory with `ulimit -l`.

The default behavior for huge pages in Postgres Pro is to use them when possible, with the system's default huge page size, and to fall back to normal pages on failure. To enforce the use of huge pages, you can set `huge_pages` to `on` in `postgresql.conf`. Note that with this setting Postgres Pro will fail to start if not enough huge pages are available.

17.5. Shutting Down the Server

There are several ways to shut down the database server. Under the hood, they all reduce to sending a signal to the supervisor `postgres` process.

If you are using a pre-packaged version of PostgreSQL, and you used its provisions for starting the server, then you should also use its provisions for stopping the server. Consult the package-level documentation for details.

When managing the server directly, you can control the type of shutdown by sending different signals to the `postgres` process:

SIGTERM

This is the *Smart Shutdown* mode. After receiving SIGTERM, the server disallows new connections, but lets existing sessions end their work normally. It shuts down only after all of the sessions terminate. If the server is in online backup mode, it additionally waits until online backup mode is no longer active. While backup mode is active, new connections will still be allowed, but only to superusers (this exception allows a superuser to connect to terminate online backup mode). If the server is in recovery when a smart shutdown is requested, recovery and streaming replication will be stopped only after all regular sessions have terminated.

SIGINT

This is the *Fast Shutdown* mode. The server disallows new connections and sends all existing server processes SIGTERM, which will cause them to abort their current transactions and exit promptly. It then waits for all server processes to exit and finally shuts down. If the server is in online backup mode, backup mode will be terminated, rendering the backup useless.

SIGQUIT

This is the *Immediate Shutdown* mode. The server will send SIGQUIT to all child processes and wait for them to terminate. If any do not terminate within 5 seconds, they will be sent SIGKILL. The supervisor server process exits as soon as all child processes have exited, without doing normal database shutdown processing. This will lead to recovery (by replaying the WAL log) upon next start-up. This is recommended only in emergencies.

The `pg_ctl` program provides a convenient interface for sending these signals to shut down the server. Alternatively, you can send the signal directly using `kill` on non-Windows systems. The PID of the
The `postgres` process can be found using the `ps` program, or from the file `postmaster.pid` in the data directory. For example, to do a fast shutdown:

\[
\text{\$ kill -INT `head -1 /usr/local/pgsql/data/postmaster.pid`}
\]

**Important**

It is best not to use SIGKILL to shut down the server. Doing so will prevent the server from releasing shared memory and semaphores. Furthermore, SIGKILL kills the `postgres` process without letting it relay the signal to its subprocesses, so it might be necessary to kill the individual subprocesses by hand as well.

To terminate an individual session while allowing other sessions to continue, use `pg_terminate_backend()` (see Table 9.86) or send a SIGTERM signal to the child process associated with the session.

## 17.6. Upgrading a Postgres Pro Cluster

This section discusses how to upgrade your database data from one Postgres Pro release to a newer one.

Current Postgres Pro version numbers consist of a major and a minor version number. For example, in the version number 10.1, the 10 is the major version number and the 1 is the minor version number, meaning this would be the first minor release of the major release 10. For releases before Postgres Pro version 10.0, version numbers consist of three numbers, for example, 9.5.3. In those cases, the major version consists of the first two digit groups of the version number, e.g., 9.5, and the minor version is the third number, e.g., 3, meaning this would be the third minor release of the major release 9.5.

Minor releases never change the internal storage format and are always compatible with earlier and later minor releases of the same major version number. For example, version 10.1 is compatible with version 10.0 and version 10.6. Similarly, for example, 9.5.3 is compatible with 9.5.0, 9.5.1, and 9.5.6. To update between compatible versions, you simply replace the executables while the server is down and restart the server. The data directory remains unchanged — minor upgrades are that simple.

For **major** releases of Postgres Pro, the internal data storage format is subject to change, thus complicating upgrades. The traditional method for moving data to a new major version is to dump and reload the database, though this can be slow. A faster method is `pg_upgrade`. Replication methods are also available, as discussed below.

New major versions also typically introduce some user-visible incompatibilities, so application programming changes might be required. All user-visible changes are listed in the release notes (Appendix E); pay particular attention to the section labeled "Migration". Though you can upgrade from one major version to another without upgrading to intervening versions, you should read the major release notes of all intervening versions.

Cautious users will want to test their client applications on the new version before switching over fully; therefore, it's often a good idea to set up concurrent installations of old and new versions. When testing a Postgres Pro major upgrade, consider the following categories of possible changes:

**Administration**

The capabilities available for administrators to monitor and control the server often change and improve in each major release.

**SQL**

Typically this includes new SQL command capabilities and not changes in behavior, unless specifically mentioned in the release notes.

**Library API**

Typically libraries like `libpq` only add new functionality, again unless mentioned in the release notes.
System Catalogs
System catalog changes usually only affect database management tools.

Server C-language API
This involves changes in the backend function API, which is written in the C programming language. Such changes affect code that references backend functions deep inside the server.

17.6.1. Upgrading Data via pg_dumpall
One upgrade method is to dump data from one major version of Postgres Pro and reload it in another — to do this, you must use a logical backup tool like pg_dumpall; file system level backup methods will not work. (There are checks in place that prevent you from using a data directory with an incompatible version of Postgres Pro, so no great harm can be done by trying to start the wrong server version on a data directory.)

It is recommended that you use the pg_dump and pg_dumpall programs from the newer version of Postgres Pro, to take advantage of enhancements that might have been made in these programs. Current releases of the dump programs can read data from any server version back to 7.0.

These instructions assume that your existing installation is under the /usr/local/pgsql directory, and that the data area is in /usr/local/pgsql/data. Substitute your paths appropriately.

1. If making a backup, make sure that your database is not being updated. This does not affect the integrity of the backup, but the changed data would of course not be included. If necessary, edit the permissions in the file /usr/local/pgsql/data/pg_hba.conf (or equivalent) to disallow access from everyone except you. See Chapter 19 for additional information on access control.

   To back up your database installation, type:
   
   `pg_dumpall > outputfile`

   To make the backup, you can use the pg_dumpall command from the version you are currently running; see Section 24.1.2 for more details. For best results, however, try to use the pg_dumpall command from Postgres Pro Standard 14.1.1, since this version contains bug fixes and improvements over older versions. While this advice might seem idiosyncratic since you haven’t installed the new version yet, it is advisable to follow it if you plan to install the new version in parallel with the old version. In that case you can complete the installation normally and transfer the data later. This will also decrease the downtime.

2. Shut down the old server:
   
   `pg_ctl stop`

   On systems that have Postgres Pro started at boot time, there is probably a start-up file that will accomplish the same thing. For example, on a Red Hat Linux system one might find that this works:
   
   `/etc/rc.d/init.d/postgresql stop`

   See Chapter 17 for details about starting and stopping the server.

3. If restoring from backup, rename or delete the old installation directory if it is not version-specific. It is a good idea to rename the directory, rather than delete it, in case you have trouble and need to revert to it. Keep in mind the directory might consume significant disk space. To rename the directory, use a command like this:
   
   `mv /usr/local/pgsql /usr/local/pgsql.old`

   (Be sure to move the directory as a single unit so relative paths remain unchanged.)

4. Install the new version of Postgres Pro Standard.

5. Create a new database cluster if needed. Remember that you must execute these commands while logged in to the special database user account (which you already have if you are upgrading).

   `/usr/local/pgsql/bin/initdb -D /usr/local/pgsql/data`
6. Restore your previous `pg_hba.conf` and any PostgreSQL.conf modifications.

7. Start the database server, again using the special database user account:
   
   ```bash
   /usr/local/pgsql/bin/postgres -D /usr/local/pgsql/data
   ```

8. Finally, restore your data from backup with:
   
   ```bash
   /usr/local/pgsql/bin/psql -d postgres -f outputfile
   ```

   using the `new` `psql`.

   The least downtime can be achieved by installing the new server in a different directory and running both the old and the new servers in parallel, on different ports. Then you can use something like:

   ```bash
   pg_dumpall -p 5432 | psql -d postgres -p 5433
   ```

to transfer your data.

### 17.6.2. Upgrading Data via `pg_upgrade`

The `pg_upgrade` module allows an installation to be migrated in-place from one major Postgres Pro version to another. Upgrades can be performed in minutes, particularly with `--link` mode. It requires steps similar to `pg_dumpall` above, e.g., starting/stopping the server, running `initdb`. The `pg_upgrade` documentation outlines the necessary steps.

### 17.6.3. Upgrading Data via Replication

It is also possible to use logical replication methods to create a standby server with the updated version of Postgres Pro. This is possible because logical replication supports replication between different major versions of Postgres Pro. The standby can be on the same computer or a different computer. Once it has synced up with the primary server (running the older version of Postgres Pro), you can switch primaries and make the standby the primary and shut down the older database instance. Such a switch-over results in only several seconds of downtime for an upgrade.

This method of upgrading can be performed using the built-in logical replication facilities as well as using external logical replication systems such as pglogical, Slony, Londiste, and Bucardo.

### 17.7. Preventing Server Spoofing

While the server is running, it is not possible for a malicious user to take the place of the normal database server. However, when the server is down, it is possible for a local user to spoof the normal server by starting their own server. The spoof server could read passwords and queries sent by clients, but could not return any data because the `PGDATA` directory would still be secure because of directory permissions. Spoofing is possible because any user can start a database server; a client cannot identify an invalid server unless it is specially configured.

One way to prevent spoofing of local connections is to use a Unix domain socket directory (`unix_socket_directories`) that has write permission only for a trusted local user. This prevents a malicious user from creating their own socket file in that directory. If you are concerned that some applications might still reference `/tmp` for the socket file and hence be vulnerable to spoofing, during operating system startup create a symbolic link `/tmp/.s.PGSQL.5432` that points to the relocated socket file. You also might need to modify your `/tmp` cleanup script to prevent removal of the symbolic link.

Another option for local connections is for clients to use `requirepeer` to specify the required owner of the server process connected to the socket.

To prevent spoofing on TCP connections, either use SSL certificates and make sure that clients check the server's certificate, or use GSSAPI encryption (or both, if they're on separate connections).

To prevent spoofing with SSL, the server must be configured to accept only hostssl connections (Section 19.1) and have SSL key and certificate files (Section 17.9). The TCP client must connect using `sslmode=verify-ca` or `verify-full` and have the appropriate root certificate file installed (Section 32.19.1).
To prevent spoofing with GSSAPI, the server must be configured to accept only hostgssenc connections (Section 19.1) and use gss authentication with them. The TCP client must connect using gssencmode=require.

17.8. Encryption Options

Postgres Pro offers encryption at several levels, and provides flexibility in protecting data from disclosure due to database server theft, unscrupulous administrators, and insecure networks. Encryption might also be required to secure sensitive data such as medical records or financial transactions.

Password Encryption

Database user passwords are stored as hashes (determined by the setting password_encryption), so the administrator cannot determine the actual password assigned to the user. If SCRAM or MD5 encryption is used for client authentication, the unencrypted password is never even temporarily present on the server because the client encrypts it before being sent across the network. SCRAM is preferred, because it is an Internet standard and is more secure than the PostgreSQL-specific MD5 authentication protocol.

Encryption For Specific Columns

The pgcrypto module allows certain fields to be stored encrypted. This is useful if only some of the data is sensitive. The client supplies the decryption key and the data is decrypted on the server and then sent to the client.

The decrypted data and the decryption key are present on the server for a brief time while it is being decrypted and communicated between the client and server. This presents a brief moment where the data and keys can be intercepted by someone with complete access to the database server, such as the system administrator.

Data Partition Encryption

Storage encryption can be performed at the file system level or the block level. Linux file system encryption options include eCryptfs and EncFS, while FreeBSD uses PEFS. Block level or full disk encryption options include dm-crypt + LUKS on Linux and GEOM modules geli and gbde on FreeBSD. Many other operating systems support this functionality, including Windows.

This mechanism prevents unencrypted data from being read from the drives if the drives or the entire computer is stolen. This does not protect against attacks while the file system is mounted, because when mounted, the operating system provides an unencrypted view of the data. However, to mount the file system, you need some way for the encryption key to be passed to the operating system, and sometimes the key is stored somewhere on the host that mounts the disk.

Encrypting Data Across A Network

SSL connections encrypt all data sent across the network: the password, the queries, and the data returned. The pg_hba.conf file allows administrators to specify which hosts can use non-encrypted connections (host) and which require SSL-encrypted connections (hostssl). Also, clients can specify that they connect to servers only via SSL.

GSSAPI-encrypted connections encrypt all data sent across the network, including queries and data returned. (No password is sent across the network.) The pg_hba.conf file allows administrators to specify which hosts can use non-encrypted connections (host) and which require GSSAPI-encrypted connections (hostgssenc). Also, clients can specify that they connect to servers only on GSSAPI-encrypted connections (gssencmode=require).

Stunnel or SSH can also be used to encrypt transmissions.

SSL Host Authentication

It is possible for both the client and server to provide SSL certificates to each other. It takes some extra configuration on each side, but this provides stronger verification of identity than the mere
use of passwords. It prevents a computer from pretending to be the server just long enough to read
the password sent by the client. It also helps prevent “man in the middle” attacks where a computer
between the client and server pretends to be the server and reads and passes all data between the
client and server.

Client-Side Encryption

If the system administrator for the server's machine cannot be trusted, it is necessary for the client to
encrypt the data; this way, unencrypted data never appears on the database server. Data is encrypted
on the client before being sent to the server, and database results have to be decrypted on the client
before being used.

17.9. Secure TCP/IP Connections with SSL

Postgres Pro has native support for using SSL connections to encrypt client/server communications for
increased security.

17.9.1. Basic Setup

With SSL support compiled in, the Postgres Pro server can be started with SSL enabled by setting the
parameter ssl to on in postgresql.conf. The server will listen for both normal and SSL connections on
the same TCP port, and will negotiate with any connecting client on whether to use SSL. By default,
this is at the client's option; see Section 19.1 about how to set up the server to require use of SSL for
some or all connections.

To start in SSL mode, files containing the server certificate and private key must exist. By default, these
files are expected to be named server.crt and server.key, respectively, in the server's data directory,
but other names and locations can be specified using the configuration parameters ssl_cert_file and
ssl_key_file.

On Unix systems, the permissions on server.key must disallow any access to world or group; achieve
this by the command chmod 0600 server.key. Alternatively, the file can be owned by root and have
group read access (that is, 0640 permissions). That setup is intended for installations where certificate
and key files are managed by the operating system. The user under which the Postgres Pro server runs
should then be made a member of the group that has access to those certificate and key files.

If the data directory allows group read access then certificate files may need to be located outside of the
data directory in order to conform to the security requirements outlined above. Generally, group access
is enabled to allow an unprivileged user to backup the database, and in that case the backup software
will not be able to read the certificate files and will likely error.

If the private key is protected with a passphrase, the server will prompt for the passphrase and will
not start until it has been entered. Using a passphrase by default disables the ability to change the
server's SSL configuration without a server restart, but see ssl passphrase command supports reload.
Furthermore, passphrase-protected private keys cannot be used at all on Windows.

The first certificate in server.crt must be the server's certificate because it must match the server's
private key. The certificates of “intermediate” certificate authorities can also be appended to the file.
Doing this avoids the necessity of storing intermediate certificates on clients, assuming the root and
intermediate certificates were created with v3_ca extensions. (This sets the certificate's basic constraint
of CA to true.) This allows easier expiration of intermediate certificates.

It is not necessary to add the root certificate to server.crt. Instead, clients must have the root certificate
of the server's certificate chain.

17.9.2. OpenSSL Configuration

Postgres Pro reads the system-wide OpenSSL configuration file. By default, this file is named
openssl.cnf and is located in the directory reported by openssl version -d. This default can be
overridden by setting environment variable OPENSSL_CONF to the name of the desired configuration file.
OpenSSL supports a wide range of ciphers and authentication algorithms, of varying strength. While a list of ciphers can be specified in the OpenSSL configuration file, you can specify ciphers specifically for use by the database server by modifying `ssl_ciphers` in `postgresql.conf`.

**Note**

It is possible to have authentication without encryption overhead by using `NULL-SHA` or `NULL-MD5` ciphers. However, a man-in-the-middle could read and pass communications between client and server. Also, encryption overhead is minimal compared to the overhead of authentication. For these reasons NULL ciphers are not recommended.

### 17.9.3. Using Client Certificates

To require the client to supply a trusted certificate, place certificates of the root certificate authorities (CAs) you trust in a file in the data directory, set the parameter `ssl_ca_file` in `postgresql.conf` to the new file name, and add the authentication option `clientcert=verify-ca` or `clientcert=verify-full` to the appropriate `hostssl` line(s) in `pg_hba.conf`. A certificate will then be requested from the client during SSL connection startup. (See Section 32.19 for a description of how to set up certificates on the client.)

For a `hostssl` entry with `clientcert=verify-ca`, the server will verify that the client's certificate is signed by one of the trusted certificate authorities. If `clientcert=verify-full` is specified, the server will not only verify the certificate chain, but it will also check whether the username or its mapping matches the `cn` (Common Name) of the provided certificate. Note that certificate chain validation is always ensured when the `cert` authentication method is used (see Section 19.12).

Intermediate certificates that chain up to existing root certificates can also appear in the `ssl_ca_file` file if you wish to avoid storing them on clients (assuming the root and intermediate certificates were created with `v3_ca` extensions). Certificate Revocation List (CRL) entries are also checked if the parameter `ssl_crl_file` is set.

The `clientcert` authentication option is available for all authentication methods, but only in `pg_hba.conf` lines specified as `hostssl`. When `clientcert` is not specified, the server verifies the client certificate against its CA file only if a client certificate is presented and the CA is configured.

There are two approaches to enforce that users provide a certificate during login.

The first approach makes use of the `cert` authentication method for `hostssl` entries in `pg_hba.conf`, such that the certificate itself is used for authentication while also providing ssl connection security. See Section 19.12 for details. (It is not necessary to specify any `clientcert` options explicitly when using the `cert` authentication method.) In this case, the `cn` (Common Name) provided in the certificate is checked against the user name or an applicable mapping.

The second approach combines any authentication method for `hostssl` entries with the verification of client certificates by setting the `clientcert` authentication option to `verify-ca` or `verify-full`. The former option only enforces that the certificate is valid, while the latter also ensures that the `cn` (Common Name) in the certificate matches the user name or an applicable mapping.

### 17.9.4. SSL Server File Usage

Table 17.2 summarizes the files that are relevant to the SSL setup on the server. (The shown file names are default names. The locally configured names could be different.)

<table>
<thead>
<tr>
<th>File</th>
<th>Contents</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>ssl_cert_file</code> ($PGDATA/server.crt)</td>
<td>server certificate</td>
<td>sent to client to indicate server’s identity</td>
</tr>
</tbody>
</table>
The server reads these files at server start and whenever the server configuration is reloaded. On Windows systems, they are also re-read whenever a new backend process is spawned for a new client connection.

If an error in these files is detected at server start, the server will refuse to start. But if an error is detected during a configuration reload, the files are ignored and the old SSL configuration continues to be used. On Windows systems, if an error in these files is detected at backend start, that backend will be unable to establish an SSL connection. In all these cases, the error condition is reported in the server log.

### 17.9.5. Creating Certificates

To create a simple self-signed certificate for the server, valid for 365 days, use the following OpenSSL command, replacing `dbhost.yourdomain.com` with the server's host name:

```bash
openssl req -new -x509 -days 365 -nodes -text -out server.crt \
-keyout server.key -subj "/CN=dbhost.yourdomain.com"
```

Then do:

```bash
chmod og-rwx server.key
```

because the server will reject the file if its permissions are more liberal than this. For more details on how to create your server private key and certificate, refer to the OpenSSL documentation.

While a self-signed certificate can be used for testing, a certificate signed by a certificate authority (CA) (usually an enterprise-wide root CA) should be used in production.

To create a server certificate whose identity can be validated by clients, first create a certificate signing request (CSR) and a public/private key file:

```bash
openssl req -new -nodes -text -out root.csr \
-keyout root.key -subj "/CN=root.yourdomain.com"
chmod og-rwx root.key
```

Then, sign the request with the key to create a root certificate authority (using the default OpenSSL configuration file location on Linux):

```bash
openssl x509 -req -in root.csr -text -days 3650 \
-extfile /etc/ssl/openssl.cnf -extensions v3_ca \
-signkey root.key -out root.crt
```

Finally, create a server certificate signed by the new root certificate authority:

```bash
openssl req -new -nodes -text -out server.csr \
-keyout server.key -subj "/CN=dbhost.yourdomain.com"
chmod og-rwx server.key
openssl x509 -req -in server.csr -text -days 365 \
-CA root.crt -CAkey root.key -CAcreateserial \ 
-out server.crt
```
server.crt and server.key should be stored on the server, and root.crt should be stored on the client so the client can verify that the server's leaf certificate was signed by its trusted root certificate. root.key should be stored offline for use in creating future certificates.

It is also possible to create a chain of trust that includes intermediate certificates:

```
# root
openssl req -new -nodes -text -out root.csr \ 
    -keyout root.key -subj "/CN=root.yourdomain.com"
chmod og-rwx root.key
openssl x509 -req -in root.csr -text -days 3650 \ 
    -extfile /etc/ssl/openssl.cnf -extensions v3_ca \ 
    -signkey root.key -out root.crt

# intermediate
openssl req -new -nodes -text -out intermediate.csr \ 
    -keyout intermediate.key -subj "/CN=intermediate.yourdomain.com"
chmod og-rwx intermediate.key
openssl x509 -req -in intermediate.csr -text -days 1825 \ 
    -extfile /etc/ssl/openssl.cnf -extensions v3_ca \ 
    -CA root.crt -CAkey root.key -CAcreateserial \ 
    -out intermediate.crt

# leaf
openssl req -new -nodes -text -out server.csr \ 
    -keyout server.key -subj "/CN=dbhost.yourdomain.com"
chmod og-rwx server.key
openssl x509 -req -in server.csr -text -days 365 \ 
    -CA intermediate.crt -CAkey intermediate.key -CAcreateserial \ 
    -out server.crt
```

server.crt and intermediate.crt should be concatenated into a certificate file bundle and stored on the server. server.key should also be stored on the server. root.crt should be stored on the client so the client can verify that the server's leaf certificate was signed by a chain of certificates linked to its trusted root certificate. root.key and intermediate.key should be stored offline for use in creating future certificates.

## 17.10. Secure TCP/IP Connections with GSSAPI Encryption

Postgres Pro also has native support for using GSSAPI to encrypt client/server communications for increased security. Support requires that a GSSAPI implementation (such as MIT Kerberos) is installed on both client and server systems, and that support in Postgres Pro is enabled at build time.

### 17.10.1. Basic Setup

The Postgres Pro server will listen for both normal and GSSAPI-encrypted connections on the same TCP port, and will negotiate with any connecting client whether to use GSSAPI for encryption (and for authentication). By default, this decision is up to the client (which means it can be downgraded by an attacker); see Section 19.1 about setting up the server to require the use of GSSAPI for some or all connections.

When using GSSAPI for encryption, it is common to use GSSAPI for authentication as well, since the underlying mechanism will determine both client and server identities (according to the GSSAPI implementation) in any case. But this is not required; another Postgres Pro authentication method can be chosen to perform additional verification.

Other than configuration of the negotiation behavior, GSSAPI encryption requires no setup beyond that which is necessary for GSSAPI authentication. (For more information on configuring that, see Section 19.6.)
17.11. Secure TCP/IP Connections with SSH Tunnels

It is possible to use SSH to encrypt the network connection between clients and a Postgres Pro server. Done properly, this provides an adequately secure network connection, even for non-SSL-capable clients.

First make sure that an SSH server is running properly on the same machine as the Postgres Pro server and that you can log in using `ssh` as some user; you then can establish a secure tunnel to the remote server. A secure tunnel listens on a local port and forwards all traffic to a port on the remote machine. Traffic sent to the remote port can arrive on its `localhost` address, or different bind address if desired; it does not appear as coming from your local machine. This command creates a secure tunnel from the client machine to the remote machine `foo.com`:

```
ssh -L 63333:localhost:5432 joe@foo.com
```

The first number in the `-L` argument, 63333, is the local port number of the tunnel; it can be any unused port. (IANA reserves ports 49152 through 65535 for private use.) The name or IP address after this is the remote bind address you are connecting to, i.e., `localhost`, which is the default. The second number, 5432, is the remote end of the tunnel, e.g., the port number your database server is using. In order to connect to the database server using this tunnel, you connect to port 63333 on the local machine:

```
psql -h localhost -p 63333 postgres
```

To the database server it will then look as though you are user `joe` on host `foo.com` connecting to the `localhost` bind address, and it will use whatever authentication procedure was configured for connections by that user to that bind address. Note that the server will not think the connection is SSL-encrypted, since in fact it is not encrypted between the SSH server and the Postgres Pro server. This should not pose any extra security risk because they are on the same machine.

In order for the tunnel setup to succeed you must be allowed to connect via `ssh as joe@foo.com`, just as if you had attempted to use `ssh` to create a terminal session.

You could also have set up port forwarding as

```
ssh -L 63333:foo.com:5432 joe@foo.com
```

but then the database server will see the connection as coming in on its `foo.com` bind address, which is not opened by the default setting `listen_addresses = 'localhost'`. This is usually not what you want.

If you have to “hop” to the database server via some login host, one possible setup could look like this:

```
ssh -L 63333:db.foo.com:5432 joe@shell.foo.com
```

Note that this way the connection from `shell.foo.com` to `db.foo.com` will not be encrypted by the SSH tunnel. SSH offers quite a few configuration possibilities when the network is restricted in various ways. Please refer to the SSH documentation for details.

Tip

Several other applications exist that can provide secure tunnels using a procedure similar in concept to the one just described.

17.12. Registering Event Log on Windows

To register a Windows event log library with the operating system, issue this command:

```
regsvr32 psql_library_directory/pgevent.dll
```

This creates registry entries used by the event viewer, under the default event source named Postgres Pro.

To specify a different event source name (see `event_source`), use the `/n` and `/i` options:
regsvr32 /n /i:event_source_name pgsq1_library_directory/pgevent.dll

To unregister the event log library from the operating system, issue this command:
regsvr32 /u [/i:event_source_name] pgsq1_library_directory/pgevent.dll

Note
To enable event logging in the database server, modify log_destination to include eventlog in postgresql.conf.
Chapter 18. Server Configuration

There are many configuration parameters that affect the behavior of the database system. In the first section of this chapter we describe how to interact with configuration parameters. The subsequent sections discuss each parameter in detail.

18.1. Setting Parameters

18.1.1. Parameter Names and Values

All parameter names are case-insensitive. Every parameter takes a value of one of five types: boolean, string, integer, floating point, or enumerated (enum). The type determines the syntax for setting the parameter:

- **Boolean**: Values can be written as `on`, `off`, `true`, `false`, `yes`, `no`, `1`, `0` (all case-insensitive) or any unambiguous prefix of one of these.

- **String**: In general, enclose the value in single quotes, doubling any single quotes within the value. Quotes can usually be omitted if the value is a simple number or identifier, however. (Values that match an SQL keyword require quoting in some contexts.)

- **Numeric (integer and floating point)**: Numeric parameters can be specified in the customary integer and floating-point formats; fractional values are rounded to the nearest integer if the parameter is of integer type. Integer parameters additionally accept hexadecimal input (beginning with `0x`) and octal input (beginning with `0`), but these formats cannot have a fraction. Do not use thousands separators. Quotes are not required, except for hexadecimal input.

- **Numeric with Unit**: Some numeric parameters have an implicit unit, because they describe quantities of memory or time. The unit might be bytes, kilobytes, blocks (typically eight kilobytes), milliseconds, seconds, or minutes. An unadorned numeric value for one of these settings will use the setting’s default unit, which can be learned from `pg_settings.unit`. For convenience, settings can be given with a unit specified explicitly, for example `'120 ms'` for a time value, and they will be converted to whatever the parameter's actual unit is. Note that the value must be written as a string (with quotes) to use this feature. The unit name is case-sensitive, and there can be whitespace between the numeric value and the unit.

  - Valid memory units are `B` (bytes), `kB` (kilobytes), `MB` (megabytes), `GB` (gigabytes), and `TB` (terabytes). The multiplier for memory units is 1024, not 1000.

  - Valid time units are `us` (microseconds), `ms` (milliseconds), `s` (seconds), `min` (minutes), `h` (hours), and `d` (days).

  If a fractional value is specified with a unit, it will be rounded to a multiple of the next smaller unit if there is one. For example, `30.1 GB` will be converted to `30822 MB` not `32319628902 B`. If the parameter is of integer type, a final rounding to integer occurs after any unit conversion.

- **Enumerated**: Enumerated-type parameters are written in the same way as string parameters, but are restricted to have one of a limited set of values. The values allowable for such a parameter can be found from `pg_settings.enumvals`. Enum parameter values are case-insensitive.

18.1.2. Parameter Interaction via the Configuration File

The most fundamental way to set these parameters is to edit the file `postgresql.conf`, which is normally kept in the data directory. A default copy is installed when the database cluster directory is initialized. An example of what this file might look like is:

```sql
# This is a comment
log_connections = yes
log_destination = 'syslog'
search_path = '$user', public
shared_buffers = 128MB
```
One parameter is specified per line. The equal sign between name and value is optional. Whitespace is insignificant (except within a quoted parameter value) and blank lines are ignored. Hash marks (#) designate the remainder of the line as a comment. Parameter values that are not simple identifiers or numbers must be single-quoted. To embed a single quote in a parameter value, write either two quotes (preferred) or backslash-quote. If the file contains multiple entries for the same parameter, all but the last one are ignored.

Parameters set in this way provide default values for the cluster. The settings seen by active sessions will be these values unless they are overridden. The following sections describe ways in which the administrator or user can override these defaults.

The configuration file is reread whenever the main server process receives a SIGHUP signal; this signal is most easily sent by running `pg_ctl reload` from the command line or by calling the SQL function `pg_reload_conf()`. The main server process also propagates this signal to all currently running server processes, so that existing sessions also adopt the new values (this will happen after they complete any currently-executing client command). Alternatively, you can send the signal to a single server process directly. Some parameters can only be set at server start; any changes to their entries in the configuration file will be ignored until the server is restarted. Invalid parameter settings in the configuration file are likewise ignored (but logged) during SIGHUP processing.

In addition to `postgresql.conf`, a Postgres Pro data directory contains a file `postgresql.auto.conf`, which has the same format as `postgresql.conf` but is intended to be edited automatically, not manually. This file holds settings provided through the `ALTER SYSTEM` command. This file is read whenever `postgresql.conf` is, and its settings take effect in the same way. Settings in `postgresql.auto.conf` override those in `postgresql.conf`.

External tools may also modify `postgresql.auto.conf`. It is not recommended to do this while the server is running, since a concurrent `ALTER SYSTEM` command could overwrite such changes. Such tools might simply append new settings to the end, or they might choose to remove duplicate settings and/or comments (as `ALTER SYSTEM` will).

The system view `pg_file_settings` can be helpful for pre-testing changes to the configuration files, or for diagnosing problems if a SIGHUP signal did not have the desired effects.

### 18.1.3. Parameter Interaction via SQL

Postgres Pro provides three SQL commands to establish configuration defaults. The already-mentioned `ALTER SYSTEM` command provides an SQL-accessible means of changing global defaults; it is functionally equivalent to editing `postgresql.conf`. In addition, there are two commands that allow setting of defaults on a per-database or per-role basis:

- The `ALTER DATABASE` command allows global settings to be overridden on a per-database basis.
- The `ALTER ROLE` command allows both global and per-database settings to be overridden with user-specific values.

Values set with `ALTER DATABASE` and `ALTER ROLE` are applied only when starting a fresh database session. They override values obtained from the configuration files or server command line, and constitute defaults for the rest of the session. Note that some settings cannot be changed after server start, and so cannot be set with these commands (or the ones listed below).

Once a client is connected to the database, Postgres Pro provides two additional SQL commands (and equivalent functions) to interact with session-local configuration settings:

- The `SHOW` command allows inspection of the current value of any parameter. The corresponding SQL function is `current_setting(setting_name text)` (see Section 9.27.1).
- The `SET` command allows modification of the current value of those parameters that can be set locally to a session; it has no effect on other sessions. The corresponding SQL function is `set_config(setting_name, new_value, is_local)` (see Section 9.27.1).

In addition, the system view `pg_settings` can be used to view and change session-local values:
• Querying this view is similar to using SHOW ALL but provides more detail. It is also more flexible, since it's possible to specify filter conditions or join against other relations.

• Using UPDATE on this view, specifically updating the setting column, is the equivalent of issuing SET commands. For example, the equivalent of

   SET configuration_parameter TO DEFAULT;

is:

   UPDATE pg_settings SET setting = reset_val WHERE name = 'configuration_parameter';

### 18.1.4. Parameter Interaction via the Shell

In addition to setting global defaults or attaching overrides at the database or role level, you can pass settings to Postgres Pro via shell facilities. Both the server and libpq client library accept parameter values via the shell.

• During server startup, parameter settings can be passed to the `postgres` command via the `-c` command-line parameter. For example,

   postgres -c log_connections=yes -c log_destination=syslog

   Settings provided in this way override those set via postgresql.conf or ALTER SYSTEM, so they cannot be changed globally without restarting the server.

• When starting a client session via libpq, parameter settings can be specified using the `PGOPTIONS` environment variable. Settings established in this way constitute defaults for the life of the session, but do not affect other sessions. For historical reasons, the format of `PGOPTIONS` is similar to that used when launching the `postgres` command; specifically, the `-c` flag must be specified. For example,

   env PGOPTIONS="-c geqo=off -c statement_timeout=5min" psql

   Other clients and libraries might provide their own mechanisms, via the shell or otherwise, that allow the user to alter session settings without direct use of SQL commands.

### 18.1.5. Managing Configuration File Contents

Postgres Pro provides several features for breaking down complex `postgresql.conf` files into sub-files. These features are especially useful when managing multiple servers with related, but not identical, configurations.

In addition to individual parameter settings, the `postgresql.conf` file can contain `include` directives, which specify another file to read and process as if it were inserted into the configuration file at this point. This feature allows a configuration file to be divided into physically separate parts. Include directives simply look like:

   include 'filename'

If the file name is not an absolute path, it is taken as relative to the directory containing the referencing configuration file. Inclusions can be nested.

There is also an `include_if_exists` directive, which acts the same as the include directive, except when the referenced file does not exist or cannot be read. A regular include will consider this an error condition, but `include_if_exists` merely logs a message and continues processing the referencing configuration file.

The `postgresql.conf` file can also contain `include_dir` directives, which specify an entire directory of configuration files to include. These look like

   include_dir 'directory'

Non-absolute directory names are taken as relative to the directory containing the referencing configuration file. Within the specified directory, only non-directory files whose names end with the suffix `.conf` will be included. File names that start with the `.` character are also ignored, to prevent mistakes
since such files are hidden on some platforms. Multiple files within an include directory are processed in file name order (according to C locale rules, i.e., numbers before letters, and uppercase letters before lowercase ones).

Include files or directories can be used to logically separate portions of the database configuration, rather than having a single large `postgresql.conf` file. Consider a company that has two database servers, each with a different amount of memory. There are likely elements of the configuration both will share, for things such as logging. But memory-related parameters on the server will vary between the two. And there might be server specific customizations, too. One way to manage this situation is to break the custom configuration changes for your site into three files. You could add this to the end of your `postgresql.conf` file to include them:

```
include 'shared.conf'
include 'memory.conf'
include 'server.conf'
```

All systems would have the same `shared.conf`. Each server with a particular amount of memory could share the same `memory.conf`; you might have one for all servers with 8GB of RAM, another for those having 16GB. And finally `server.conf` could have truly server-specific configuration information in it.

Another possibility is to create a configuration file directory and put this information into files there. For example, a `conf.d` directory could be referenced at the end of `postgresql.conf`:

```
include_dir 'conf.d'
```

Then you could name the files in the `conf.d` directory like this:

```
00shared.conf
01memory.conf
02server.conf
```

This naming convention establishes a clear order in which these files will be loaded. This is important because only the last setting encountered for a particular parameter while the server is reading configuration files will be used. In this example, something set in `conf.d/02server.conf` would override a value set in `conf.d/01memory.conf`.

You might instead use this approach to naming the files descriptively:

```
00shared.conf
01memory-8GB.conf
02server-foo.conf
```

This sort of arrangement gives a unique name for each configuration file variation. This can help eliminate ambiguity when several servers have their configurations all stored in one place, such as in a version control repository. (Storing database configuration files under version control is another good practice to consider.)

### 18.2. File Locations

In addition to the `postgresql.conf` file already mentioned, Postgres Pro uses two other manually-edited configuration files, which control client authentication (their use is discussed in Chapter 19). By default, all three configuration files are stored in the database cluster's data directory. The parameters described in this section allow the configuration files to be placed elsewhere. (Doing so can ease administration. In particular it is often easier to ensure that the configuration files are properly backed-up when they are kept separate.)

Parameter: `data_directory`

Specifies the directory to use for data storage. This parameter can only be set at server start.

Parameter: `config_file`

Specifies the main server configuration file (customarily called `postgresql.conf`). This parameter can only be set on the `postgres` command line.
hba_file (string)

Specifies the configuration file for host-based authentication (customarily called pg_hba.conf). This parameter can only be set at server start.

ident_file (string)

Specifies the configuration file for user name mapping (customarily called pg_ident.conf). This parameter can only be set at server start. See also Section 19.2.

external_pid_file (string)

Specifies the name of an additional process-ID (PID) file that the server should create for use by server administration programs. This parameter can only be set at server start.

In a default installation, none of the above parameters are set explicitly. Instead, the data directory is specified by the -D command-line option or the PGDATA environment variable, and the configuration files are all found within the data directory.

If you wish to keep the configuration files elsewhere than the data directory, the postgres -D command-line option or PGDATA environment variable must point to the directory containing the configuration files, and the data_directory parameter must be set in postgresql.conf (or on the command line) to show where the data directory is actually located. Notice that data_directory overrides -D and PGDATA for the location of the data directory, but not for the location of the configuration files.

If you wish, you can specify the configuration file names and locations individually using the parameters config_file, hba_file and/or ident_file. config_file can only be specified on the postgres command line, but the others can be set within the main configuration file. If all three parameters plus data_directory are explicitly set, then it is not necessary to specify -D or PGDATA.

When setting any of these parameters, a relative path will be interpreted with respect to the directory in which postgres is started.

18.3. Connections and Authentication

18.3.1. Connection Settings

listen_addresses (string)

Specifies the TCP/IP address(es) on which the server is to listen for connections from client applications. The value takes the form of a comma-separated list of host names and/or numeric IP addresses. The special entry * corresponds to all available IP interfaces. The entry 0.0.0.0 allows listening for all IPv4 addresses and :: allows listening for all IPv6 addresses. If the list is empty, the server does not listen on any IP interface at all, in which case only Unix-domain sockets can be used to connect to it. The default value is localhost, which allows only local TCP/IP “loopback” connections to be made. While client authentication (Chapter 19) allows fine-grained control over who can access the server, listen_addresses controls which interfaces accept connection attempts, which can help prevent repeated malicious connection requests on insecure network interfaces. This parameter can only be set at server start.

port (integer)

The TCP port the server listens on; 5432 by default. Note that the same port number is used for all IP addresses the server listens on. This parameter can only be set at server start.

max_connections (integer)

Determines the maximum number of concurrent connections to the database server. The default is typically 100 connections, but might be less if your kernel settings will not support it (as determined during initdb). This parameter can only be set at server start.

When running a standby server, you must set this parameter to the same or higher value than on the primary server. Otherwise, queries will not be allowed in the standby server.
superuser_reserved_connections (integer)

Determines the number of connection “slots” that are reserved for connections by Postgres Pro superusers. At most max_connections connections can ever be active simultaneously. Whenever the number of active concurrent connections is at least max_connections minus superuser_reserved_connections, new connections will be accepted only for superusers, and no new replication connections will be accepted.

The default value is three connections. The value must be less than max_connections. This parameter can only be set at server start.

unix_socket_directories (string)

Specifies the directory of the Unix-domain socket(s) on which the server is to listen for connections from client applications. Multiple sockets can be created by listing multiple directories separated by commas. Whitespace between entries is ignored; surround a directory name with double quotes if you need to include whitespace or commas in the name. An empty value specifies not listening on any Unix-domain sockets, in which case only TCP/IP sockets can be used to connect to the server.

A value that starts with @ specifies that a Unix-domain socket in the abstract namespace should be created (currently supported on Linux and Windows). In that case, this value does not specify a “directory” but a prefix from which the actual socket name is computed in the same manner as for the file-system namespace. While the abstract socket name prefix can be chosen freely, since it is not a file-system location, the convention is to nonetheless use file-system-like values such as @/tmp.

The default value is normally /tmp, but that can be changed at build time. On Windows, the default is empty, which means no Unix-domain socket is created by default. This parameter can only be set at server start.

In addition to the socket file itself, which is named .s.PGSQL.nnnn where nnnn is the server's port number, an ordinary file named .s.PGSQL.nnnn.lock will be created in each of the unix_socket_directories directories. Neither file should ever be removed manually. For sockets in the abstract namespace, no lock file is created.

unix_socket_group (string)

Sets the owning group of the Unix-domain socket(s). (The owning user of the sockets is always the user that starts the server.) In combination with the parameter unix_socket_permissions this can be used as an additional access control mechanism for Unix-domain connections. By default this is the empty string, which uses the default group of the server user. This parameter can only be set at server start.

This parameter is not supported on Windows. Any setting will be ignored. Also, sockets in the abstract namespace have no file owner, so this setting is also ignored in that case.

unix_socket_permissions (integer)

Sets the access permissions of the Unix-domain socket(s). Unix-domain sockets use the usual Unix file system permission set. The parameter value is expected to be a numeric mode specified in the format accepted by the chmod and umask system calls. (To use the customary octal format the number must start with a 0 (zero).)

The default permissions are 0777, meaning anyone can connect. Reasonable alternatives are 0770 (only user and group, see also unix_socket_group) and 0700 (only user). (Note that for a Unix-domain socket, only write permission matters, so there is no point in setting or revoking read or execute permissions.)

This access control mechanism is independent of the one described in Chapter 19.

This parameter can only be set at server start.
This parameter is irrelevant on systems, notably Solaris as of Solaris 10, that ignore socket permissions entirely. There, one can achieve a similar effect by pointing `unix_socket_directories` to a directory having search permission limited to the desired audience.

Sockets in the abstract namespace have no file permissions, so this setting is also ignored in that case.

**bonjour (boolean)**

Enables advertising the server's existence via Bonjour. The default is off. This parameter can only be set at server start.

**bonjour_name (string)**

Specifies the Bonjour service name. The computer name is used if this parameter is set to the empty string `' '` (which is the default). This parameter is ignored if the server was not compiled with Bonjour support. This parameter can only be set at server start.

**tcp_keepalives_idle (integer)**

Specifies the amount of time with no network activity after which the operating system should send a TCP keepalive message to the client. If this value is specified without units, it is taken as seconds. A value of 0 (the default) selects the operating system's default. This parameter is supported only on systems that support `TCP_KEEPIDLE` or an equivalent socket option, and on Windows; on other systems, it must be zero. In sessions connected via a Unix-domain socket, this parameter is ignored and always reads as zero.

**Note**

On Windows, setting a value of 0 will set this parameter to 2 hours, since Windows does not provide a way to read the system default value.

**tcp_keepalives_interval (integer)**

Specifies the amount of time after which a TCP keepalive message that has not been acknowledged by the client should be retransmitted. If this value is specified without units, it is taken as seconds. A value of 0 (the default) selects the operating system's default. This parameter is supported only on systems that support `TCP_KEEPINTVL` or an equivalent socket option, and on Windows; on other systems, it must be zero. In sessions connected via a Unix-domain socket, this parameter is ignored and always reads as zero.

**Note**

On Windows, setting a value of 0 will set this parameter to 1 second, since Windows does not provide a way to read the system default value.

**tcp_keepalives_count (integer)**

Specifies the number of TCP keepalive messages that can be lost before the server's connection to the client is considered dead. A value of 0 (the default) selects the operating system's default. This parameter is supported only on systems that support `TCP_KEEPCNT` or an equivalent socket option; on other systems, it must be zero. In sessions connected via a Unix-domain socket, this parameter is ignored and always reads as zero.

**Note**

This parameter is not supported on Windows, and must be zero.
Server Configuration

**tcp_user_timeout (integer)**

Specifies the amount of time that transmitted data may remain unacknowledged before the TCP connection is forcibly closed. If this value is specified without units, it is taken as milliseconds. A value of 0 (the default) selects the operating system's default. This parameter is supported only on systems that support TCP_USER_TIMEOUT; on other systems, it must be zero. In sessions connected via a Unix-domain socket, this parameter is ignored and always reads as zero.

```
Note
This parameter is not supported on Windows, and must be zero.
```

**client_connection_check_interval (integer)**

Sets the time interval between optional checks that the client is still connected, while running queries. The check is performed by polling the socket, and allows long running queries to be aborted sooner if the kernel reports that the connection is closed.

This option is currently available only on systems that support the non-standard POLLRDHUP extension to the poll system call, including Linux.

If the value is specified without units, it is taken as milliseconds. The default value is 0, which disables connection checks. Without connection checks, the server will detect the loss of the connection only at the next interaction with the socket, when it waits for, receives or sends data.

For the kernel itself to detect lost TCP connections reliably and within a known timeframe in all scenarios including network failure, it may also be necessary to adjust the TCP keepalive settings of the operating system, or the tcp_keepalives_idle, tcp_keepalives_interval and tcp_keepalives_count settings of PostgreSQL.

### 18.3.2. Authentication

**authentication_timeout (integer)**

Maximum amount of time allowed to complete client authentication. If a would-be client has not completed the authentication protocol in this much time, the server closes the connection. This prevents hung clients from occupying a connection indefinitely. If this value is specified without units, it is taken as seconds. The default is one minute (1m). This parameter can only be set in the `postgresql.conf` file or on the server command line.

**password_encryption (enum)**

When a password is specified in `CREATE ROLE` or `ALTER ROLE`, this parameter determines the algorithm to use to encrypt the password. Possible values are `scram-sha-256`, which will encrypt the password with SCRAM-SHA-256, and `md5`, which stores the password as an MD5 hash. The default is `scram-sha-256`.

Note that older clients might lack support for the SCRAM authentication mechanism, and hence not work with passwords encrypted with SCRAM-SHA-256. See Section 19.5 for more details.

**krb_server_keyfile (string)**

Sets the location of the server's Kerberos key file. The default is `FILE:/usr/local/pgsql/etc/krb5.keytab` (where the directory part is whatever was specified as `sysconfdir` at build time; use `pg_config --sysconfdir` to determine that). If this parameter is set to an empty string, it is ignored and a system-dependent default is used. This parameter can only be set in the `postgresql.conf` file or on the server command line. See Section 19.6 for more information.

**krb_caseins_users (boolean)**

Sets whether GSSAPI user names should be treated case-insensitively. The default is `off` (case sensitive). This parameter can only be set in the `postgresql.conf` file or on the server command line.
Server Configuration

**db_user_namespace (boolean)**

This parameter enables per-database user names. It is off by default. This parameter can only be set in the `postgresql.conf` file or on the server command line.

If this is on, you should create users as `username@dbname`. When `username` is passed by a connecting client, `@` and the database name are appended to the user name and that database-specific user name is looked up by the server. Note that when you create users with names containing `@` within the SQL environment, you will need to quote the user name.

With this parameter enabled, you can still create ordinary global users. Simply append `@` when specifying the user name in the client, e.g., `joe@`. The `@` will be stripped off before the user name is looked up by the server.

`db_user_namespace` causes the client's and server's user name representation to differ. Authentication checks are always done with the server's user name so authentication methods must be configured for the server's user name, not the client's. Because `md5` uses the user name as salt on both the client and server, `md5` cannot be used with `db_user_namespace`.

**Note**

This feature is intended as a temporary measure until a complete solution is found. At that time, this option will be removed.

### 18.3.3. SSL

See Section 17.9 for more information about setting up SSL.

**ssl (boolean)**

Enables SSL connections. This parameter can only be set in the `postgresql.conf` file or on the server command line. The default is `off`.

**ssl_ca_file (string)**

Specifies the name of the file containing the SSL server certificate authority (CA). Relative paths are relative to the data directory. This parameter can only be set in the `postgresql.conf` file or on the server command line. The default is empty, meaning no CA file is loaded, and client certificate verification is not performed.

**ssl_cert_file (string)**

Specifies the name of the file containing the SSL server certificate. Relative paths are relative to the data directory. This parameter can only be set in the `postgresql.conf` file or on the server command line. The default is `server.crt`.

**ssl_crl_file (string)**

Specifies the name of the file containing the SSL server certificate revocation list (CRL). Relative paths are relative to the data directory. This parameter can only be set in the `postgresql.conf` file or on the server command line. The default is empty, meaning no CRL file is loaded (unless `ssl_crl_dir` is set).

**ssl_crl_dir (string)**

Specifies the name of the directory containing the SSL server certificate revocation list (CRL). Relative paths are relative to the data directory. This parameter can only be set in the `postgresql.conf` file or on the server command line. The default is empty, meaning no CRLs are used (unless `ssl_crl_file` is set).
The directory needs to be prepared with the OpenSSL command `openssl rehash` or `c_rehash`. See its documentation for details.

When using this setting, CRLs in the specified directory are loaded on-demand at connection time. New CRLs can be added to the directory and will be used immediately. This is unlike `ssl_crl_file`, which causes the CRL in the file to be loaded at server start time or when the configuration is reloaded. Both settings can be used together.

**ssl_key_file (string)**

Specifies the name of the file containing the SSL server private key. Relative paths are relative to the data directory. This parameter can only be set in the `postgresql.conf` file or on the server command line. The default is `server.key`.

**ssl_ciphers (string)**

Specifies a list of SSL cipher suites that are allowed to be used by SSL connections. See the ciphers manual page in the OpenSSL package for the syntax of this setting and a list of supported values. Only connections using TLS version 1.2 and lower are affected. There is currently no setting that controls the cipher choices used by TLS version 1.3 connections. The default value is `HIGH:MEDIUM:+3DES:!aNULL`. The default is usually a reasonable choice unless you have specific security requirements.

This parameter can only be set in the `postgresql.conf` file or on the server command line.

Explanation of the default value:

- **HIGH**
  - Cipher suites that use ciphers from `HIGH` group (e.g., AES, Camellia, 3DES)

- **MEDIUM**
  - Cipher suites that use ciphers from `MEDIUM` group (e.g., RC4, SEED)

- **+3DES**
  - The OpenSSL default order for `HIGH` is problematic because it orders 3DES higher than AES128. This is wrong because 3DES offers less security than AES128, and it is also much slower. `+3DES` reorders it after all other `HIGH` and `MEDIUM` ciphers.

- **!aNULL**
  - Disables anonymous cipher suites that do no authentication. Such cipher suites are vulnerable to MITM attacks and therefore should not be used.

Available cipher suite details will vary across OpenSSL versions. Use the command `openssl ciphers -v 'HIGH:MEDIUM:+3DES:!aNULL'` to see actual details for the currently installed OpenSSL version. Note that this list is filtered at run time based on the server key type.

**ssl_prefer_server_ciphers (boolean)**

Specifies whether to use the server's SSL cipher preferences, rather than the client's. This parameter can only be set in the `postgresql.conf` file or on the server command line. The default is `on`.

Older Postgres Pro versions do not have this setting and always use the client's preferences. This setting is mainly for backward compatibility with those versions. Using the server's preferences is usually better because it is more likely that the server is appropriately configured.

**ssl_ecdh_curve (string)**

Specifies the name of the curve to use in ECDH key exchange. It needs to be supported by all clients that connect. It does not need to be the same curve used by the server's Elliptic Curve key. This parameter can only be set in the `postgresql.conf` file or on the server command line. The default is `prime256v1`. 

OpenSSL names for the most common curves are: \texttt{prime256v1} (NIST P-256), \texttt{secp384r1} (NIST P-384), \texttt{secp521r1} (NIST P-521). The full list of available curves can be shown with the command \texttt{openssl ecparam -list_curves}. Not all of them are usable in TLS though.

\texttt{ssl_min_protocol_version} (enum)

Sets the minimum SSL/TLS protocol version to use. Valid values are currently: TLSv1, TLSv1.1, TLSv1.2, TLSv1.3. Older versions of the OpenSSL library do not support all values; an error will be raised if an unsupported setting is chosen. Protocol versions before TLS 1.0, namely SSL version 2 and 3, are always disabled.

The default is TLSv1.2, which satisfies industry best practices as of this writing.

This parameter can only be set in the \texttt{postgresql.conf} file or on the server command line.

\texttt{ssl_max_protocol_version} (enum)

Sets the maximum SSL/TLS protocol version to use. Valid values are as for \texttt{ssl_min_protocol_version}, with addition of an empty string, which allows any protocol version. The default is to allow any version. Setting the maximum protocol version is mainly useful for testing or if some component has issues working with a newer protocol.

This parameter can only be set in the \texttt{postgresql.conf} file or on the server command line.

\texttt{ssl_dh_params_file} (string)

Specifies the name of the file containing Diffie-Hellman parameters used for so-called ephemeral DH family of SSL ciphers. The default is empty, in which case compiled-in default DH parameters used. Using custom DH parameters reduces the exposure if an attacker manages to crack the well-known compiled-in DH parameters. You can create your own DH parameters file with the command \texttt{openssl dhparam -out dhparams.pem 2048}.

This parameter can only be set in the \texttt{postgresql.conf} file or on the server command line.

\texttt{ssl_passphrase_command} (string)

Sets an external command to be invoked when a passphrase for decrypting an SSL file such as a private key needs to be obtained. By default, this parameter is empty, which means the built-in prompting mechanism is used.

The command must print the passphrase to the standard output and exit with code 0. In the parameter value, \%p is replaced by a prompt string. (Write \%\% for a literal \%.) Note that the prompt string will probably contain whitespace, so be sure to quote adequately. A single newline is stripped from the end of the output if present.

The command does not actually have to prompt the user for a passphrase. It can read it from a file, obtain it from a keychain facility, or similar. It is up to the user to make sure the chosen mechanism is adequately secure.

This parameter can only be set in the \texttt{postgresql.conf} file or on the server command line.

\texttt{ssl_passphrase_command_supports_reload} (boolean)

This parameter determines whether the passphrase command set by \texttt{ssl_passphrase_command} will also be called during a configuration reload if a key file needs a passphrase. If this parameter is off (the default), then \texttt{ssl_passphrase_command} will be ignored during a reload and the SSL configuration will not be reloaded if a passphrase is needed. That setting is appropriate for a command that requires a TTY for prompting, which might not be available when the server is running. Setting this parameter to on might be appropriate if the passphrase is obtained from a file, for example.

This parameter can only be set in the \texttt{postgresql.conf} file or on the server command line.
18.4. Resource Consumption

18.4.1. Memory

`shared_buffers (integer)`

Sets the amount of memory the database server uses for shared memory buffers. The default is typically 128 megabytes (128MB), but might be less if your kernel settings will not support it (as determined during initdb). This setting must be at least 128 kilobytes. However, settings significantly higher than the minimum are usually needed for good performance. If this value is specified without units, it is taken as blocks, that is $\text{BLCKSZ}$ bytes, typically 8kB. (Non-default values of $\text{BLCKSZ}$ change the minimum value.) This parameter can only be set at server start.

If you have a dedicated database server with 1GB or more of RAM, a reasonable starting value for `shared_buffers` is 25% of the memory in your system. There are some workloads where even larger settings for `shared_buffers` are effective, but because Postgres Pro also relies on the operating system cache, it is unlikely that an allocation of more than 40% of RAM to `shared_buffers` will work better than a smaller amount. Larger settings for `shared_buffers` usually require a corresponding increase in `max_wal_size`, in order to spread out the process of writing large quantities of new or changed data over a longer period of time.

On systems with less than 1GB of RAM, a smaller percentage of RAM is appropriate, so as to leave adequate space for the operating system.

`huge_pages (enum)`

Controls whether huge pages are requested for the main shared memory area. Valid values are `try` (the default), `on`, and `off`. With `huge_pages` set to `try`, the server will try to request huge pages, but fall back to the default if that fails. With `on`, failure to request huge pages will prevent the server from starting up. With `off`, huge pages will not be requested.

At present, this setting is supported only on Linux and Windows. The setting is ignored on other systems when set to `try`. On Linux, it is only supported when `shared_memory_type` is set to `mmap` (the default).

The use of huge pages results in smaller page tables and less CPU time spent on memory management, increasing performance. For more details about using huge pages on Linux, see Section 17.4.5.

Huge pages are known as large pages on Windows. To use them, you need to assign the user right “Lock pages in memory” to the Windows user account that runs Postgres Pro. You can use Windows Group Policy tool (gpedit.msc) to assign the user right “Lock pages in memory”. To start the database server on the command prompt as a standalone process, not as a Windows service, the command prompt must be run as an administrator or User Access Control (UAC) must be disabled. When the UAC is enabled, the normal command prompt revokes the user right “Lock pages in memory” when started.

Note that this setting only affects the main shared memory area. Operating systems such as Linux, FreeBSD, and Illumos can also use huge pages (also known as “super” pages or “large” pages) automatically for normal memory allocation, without an explicit request from Postgres Pro. On Linux, this is called “transparent huge pages” (THP). That feature has been known to cause performance degradation with Postgres Pro for some users on some Linux versions, so its use is currently discouraged (unlike explicit use of `huge_pages`).

`huge_page_size (integer)`

Controls the size of huge pages, when they are enabled with `huge_pages`. The default is zero (0). When set to 0, the default huge page size on the system will be used. This parameter can only be set at server start.
Some commonly available page sizes on modern 64 bit server architectures include: 2MB and 1GB (Intel and AMD), 16MB and 16GB (IBM POWER), and 64kB, 2MB, 32MB and 1GB (ARM). For more information about usage and support, see Section 17.4.5.

Non-default settings are currently supported only on Linux.

temp_buffers (integer)

Sets the maximum amount of memory used for temporary buffers within each database session. These are session-local buffers used only for access to temporary tables. If this value is specified without units, it is taken as blocks, that is $BLCKSZ$ bytes, typically 8kB. The default is eight megabytes (8MB). (If $BLCKSZ$ is not 8kB, the default value scales proportionally to it.) This setting can be changed within individual sessions, but only before the first use of temporary tables within the session; subsequent attempts to change the value will have no effect on that session.

A session will allocate temporary buffers as needed up to the limit given by temp_buffers. The cost of setting a large value in sessions that do not actually need many temporary buffers is only a buffer descriptor, or about 64 bytes, per increment in temp_buffers. However if a buffer is actually used an additional 8192 bytes will be consumed for it (or in general, $BLCKSZ$ bytes).

max_prepared_transactions (integer)

Sets the maximum number of transactions that can be in the “prepared” state simultaneously (see PREPARE TRANSACTION). Setting this parameter to zero (which is the default) disables the prepared-transaction feature. This parameter can only be set at server start.

If you are not planning to use prepared transactions, this parameter should be set to zero to prevent accidental creation of prepared transactions. If you are using prepared transactions, you will probably want max_prepared_transactions to be at least as large as max_connections, so that every session can have a prepared transaction pending.

When running a standby server, you must set this parameter to the same or higher value than on the primary server. Otherwise, queries will not be allowed in the standby server.

work_mem (integer)

Sets the base maximum amount of memory to be used by a query operation (such as a sort or hash table) before writing to temporary disk files. If this value is specified without units, it is taken as kilobytes. The default value is four megabytes (4MB). Note that for a complex query, several sort or hash operations might be running in parallel; each operation will generally be allowed to use as much memory as this value specifies before it starts to write data into temporary files. Also, several running sessions could be doing such operations concurrently. Therefore, the total memory used could be many times the value of work_mem; it is necessary to keep this fact in mind when choosing the value. Sort operations are used for ORDER BY, DISTINCT, and merge joins. Hash tables are used in hash joins, hash-based aggregation, result cache nodes and hash-based processing of IN subqueries.

Hash-based operations are generally more sensitive to memory availability than equivalent sort-based operations. The memory available for hash tables is computed by multiplying work_mem by hash_mem_multiplier. This makes it possible for hash-based operations to use an amount of memory that exceeds the usual work_mem base amount.

hash_mem_multiplier (floating point)

Used to compute the maximum amount of memory that hash-based operations can use. The final limit is determined by multiplying work_mem by hash_mem_multiplier. The default value is 1.0, which makes hash-based operations subject to the same simple work_mem maximum as sort-based operations.

Consider increasing hash_mem_multiplier in environments where spilling by query operations is a regular occurrence, especially when simply increasing work_mem results in memory pressure (memory pressure typically takes the form of intermittent out of memory errors). A setting of 1.5 or
2.0 may be effective with mixed workloads. Higher settings in the range of 2.0 - 8.0 or more may be effective in environments where `work_mem` has already been increased to 40MB or more.

`maintenance_work_mem` (integer)

Specifies the maximum amount of memory to be used by maintenance operations, such as `VACUUM`, `CREATE INDEX`, and `ALTER TABLE ADD FOREIGN KEY`. If this value is specified without units, it is taken as kilobytes. It defaults to 64 megabytes (64MB). Since only one of these operations can be executed at a time by a database session, and an installation normally doesn't have many of them running concurrently, it's safe to set this value significantly larger than `work_mem`. Larger settings might improve performance for vacuuming and for restoring database dumps.

Note that when autovacuum runs, up to `autovacuum_max_workers` times this memory may be allocated, so be careful not to set the default value too high. It may be useful to control for this by separately setting `autovacuum_work_mem`.

Note that for the collection of dead tuple identifiers, `VACUUM` is only able to utilize up to a maximum of 1GB of memory.

`autovacuum_work_mem` (integer)

Specifies the maximum amount of memory to be used by each autovacuum worker process. If this value is specified without units, it is taken as kilobytes. It defaults to -1, indicating that the value of `maintenance_work_mem` should be used instead. The setting has no effect on the behavior of `VACUUM` when run in other contexts. This parameter can only be set in the `postgresql.conf` file or on the server command line.

For the collection of dead tuple identifiers, autovacuum is only able to utilize up to a maximum of 1GB of memory, so setting `autovacuum_work_mem` to a value higher than that has no effect on the number of dead tuples that autovacuum can collect while scanning a table.

`logical_decoding_work_mem` (integer)

Specifies the maximum amount of memory to be used by logical decoding, before some of the decoded changes are written to local disk. This limits the amount of memory used by logical streaming replication connections. It defaults to 64 megabytes (64MB). Since each replication connection only uses a single buffer of this size, and an installation normally doesn't have many such connections concurrently (as limited by `max_wal_senders`), it's safe to set this value significantly higher than `work_mem`, reducing the amount of decoded changes written to disk.

`max_stack_depth` (integer)

Specifies the maximum safe depth of the server's execution stack. The ideal setting for this parameter is the actual stack size limit enforced by the kernel (as set by `ulimit -s` or local equivalent), less a safety margin of a megabyte or so. The safety margin is needed because the stack depth is not checked in every routine in the server, but only in key potentially-recursive routines. If this value is specified without units, it is taken as kilobytes. The default setting is two megabytes (2MB), which is conservatively small and unlikely to risk crashes. However, it might be too small to allow execution of complex functions. Only superusers can change this setting.

Setting `max_stack_depth` higher than the actual kernel limit will mean that a runaway recursive function can crash an individual backend process. On platforms where Postgres Pro can determine the kernel limit, the server will not allow this variable to be set to an unsafe value. However, not all platforms provide the information, so caution is recommended in selecting a value.

`shared_memory_type` (enum)

Specifies the shared memory implementation that the server should use for the main shared memory region that holds Postgres Pro's shared buffers and other shared data. Possible values are `mmap` (for anonymous shared memory allocated using `mmap`), `sysv` (for System V shared memory allocated via `shmget`) and `windows` (for Windows shared memory). Not all values are supported on all platforms;
the first supported option is the default for that platform. The use of the `sysv` option, which is not the default on any platform, is generally discouraged because it typically requires non-default kernel settings to allow for large allocations (see Section 17.4.1).

dynamic_shared_memory_type (enum)  
Specifies the dynamic shared memory implementation that the server should use. Possible values are `posix` (for POSIX shared memory allocated using `shm_open`), `sysv` (for System V shared memory allocated via `shmget`), `windows` (for Windows shared memory), and `mmap` (to simulate shared memory using memory-mapped files stored in the data directory). Not all values are supported on all platforms; the first supported option is the default for that platform. The use of the `mmap` option, which is not the default on any platform, is generally discouraged because the operating system may write modified pages back to disk repeatedly, increasing system I/O load; however, it may be useful for debugging, when the `pg_dynshmem` directory is stored on a RAM disk, or when other shared memory facilities are not available.

min_dynamic_shared_memory (integer)  
Specifies the amount of memory that should be allocated at server startup for use by parallel queries. When this memory region is insufficient or exhausted by concurrent queries, new parallel queries try to allocate extra shared memory temporarily from the operating system using the method configured with `dynamic_shared_memory_type`, which may be slower due to memory management overheads. Memory that is allocated at startup with `min_dynamic_shared_memory` is affected by the `huge_pages` setting on operating systems where that is supported, and may be more likely to benefit from larger pages on operating systems where that is managed automatically. The default value is 0 (none). This parameter can only be set at server start.

### 18.4.2. Disk

**temp_file_limit (integer)**  
Specifies the maximum amount of disk space that a process can use for temporary files, such as sort and hash temporary files, or the storage file for a held cursor. A transaction attempting to exceed this limit will be canceled. If this value is specified without units, it is taken as kilobytes. -1 (the default) means no limit. Only superusers can change this setting.

This setting constrains the total space used at any instant by all temporary files used by a given Postgres Pro process. It should be noted that disk space used for explicit temporary tables, as opposed to temporary files used behind-the-scenes in query execution, does not count against this limit.

### 18.4.3. Kernel Resource Usage

**max_files_per_process (integer)**  
Sets the maximum number of simultaneously open files allowed to each server subprocess. The default is one thousand files. If the kernel is enforcing a safe per-process limit, you don't need to worry about this setting. But on some platforms (notably, most BSD systems), the kernel will allow individual processes to open many more files than the system can actually support if many processes all try to open that many files. If you find yourself seeing “Too many open files” failures, try reducing this setting. This parameter can only be set at server start.

### 18.4.4. Cost-based Vacuum Delay

During the execution of VACUUM and ANALYZE commands, the system maintains an internal counter that keeps track of the estimated cost of the various I/O operations that are performed. When the accumulated cost reaches a limit (specified by `vacuum_cost_limit`), the process performing the operation will sleep for a short period of time, as specified by `vacuum_cost_delay`. Then it will reset the counter and continue execution.

The intent of this feature is to allow administrators to reduce the I/O impact of these commands on concurrent database activity. There are many situations where it is not important that maintenance
commands like VACUUM and ANALYZE finish quickly; however, it is usually very important that these commands do not significantly interfere with the ability of the system to perform other database operations. Cost-based vacuum delay provides a way for administrators to achieve this.

This feature is disabled by default for manually issued VACUUM commands. To enable it, set the vacuum_cost_delay variable to a nonzero value.

**vacuum_cost_delay** *(floating point)*

The amount of time that the process will sleep when the cost limit has been exceeded. If this value is specified without units, it is taken as milliseconds. The default value is zero, which disables the cost-based vacuum delay feature. Positive values enable cost-based vacuuming.

When using cost-based vacuuming, appropriate values for vacuum_cost_delay are usually quite small, perhaps less than 1 millisecond. While vacuum_cost_delay can be set to fractional-millisecond values, such delays may not be measured accurately on older platforms. On such platforms, increasing VACUUM’s throttled resource consumption above what you get at 1ms will require changing the other vacuum cost parameters. You should, nonetheless, keep vacuum_cost_delay as small as your platform will consistently measure; large delays are not helpful.

**vacuum_cost_page_hit** *(integer)*

The estimated cost for vacuuming a buffer found in the shared buffer cache. It represents the cost to lock the buffer pool, lookup the shared hash table and scan the content of the page. The default value is one.

**vacuum_cost_page_miss** *(integer)*

The estimated cost for vacuuming a buffer that has to be read from disk. This represents the effort to lock the buffer pool, lookup the shared hash table, read the desired block in from the disk and scan its content. The default value is 2.

**vacuum_cost_page_dirty** *(integer)*

The estimated cost charged when vacuum modifies a block that was previously clean. It represents the extra I/O required to flush the dirty block out to disk again. The default value is 20.

**vacuum_cost_limit** *(integer)*

The accumulated cost that will cause the vacuuming process to sleep. The default value is 200.

**Note**

There are certain operations that hold critical locks and should therefore complete as quickly as possible. Cost-based vacuum delays do not occur during such operations. Therefore it is possible that the cost accumulates far higher than the specified limit. To avoid uselessly long delays in such cases, the actual delay is calculated as vacuum_cost_delay * accumulated_balance / vacuum_cost_limit with a maximum of vacuum_cost_delay * 4.

### 18.4.5. Background Writer

There is a separate server process called the background writer, whose function is to issue writes of “dirty” (new or modified) shared buffers. When the number of clean shared buffers appears to be insufficient, the background writer writes some dirty buffers to the file system and marks them as clean. This reduces the likelihood that server processes handling user queries will be unable to find clean buffers and have to write dirty buffers themselves. However, the background writer does cause a net overall increase in I/O load, because while a repeatedly-dirtied page might otherwise be written only once per checkpoint interval, the background writer might write it several times as it is dirtied in the same interval. The parameters discussed in this subsection can be used to tune the behavior for local needs.
bgwriter_delay (integer)

Specifies the delay between activity rounds for the background writer. In each round the writer issues writes for some number of dirty buffers (controllable by the following parameters). It then sleeps for the length of bgwriter_delay, and repeats. When there are no dirty buffers in the buffer pool, though, it goes into a longer sleep regardless of bgwriter_delay. If this value is specified without units, it is taken as milliseconds. The default value is 200 milliseconds (200ms). Note that on many systems, the effective resolution of sleep delays is 10 milliseconds; setting bgwriter_delay to a value that is not a multiple of 10 might have the same results as setting it to the next higher multiple of 10. This parameter can only be set in the postgresql.conf file or on the server command line.

bgwriter_lru_maxpages (integer)

In each round, no more than this many buffers will be written by the background writer. Setting this to zero disables background writing. (Note that checkpoints, which are managed by a separate, dedicated auxiliary process, are unaffected.) The default value is 100 buffers. This parameter can only be set in the postgresql.conf file or on the server command line.

bgwriter_lru_multiplier (floating point)

The number of dirty buffers written in each round is based on the number of new buffers that have been needed by server processes during recent rounds. The average recent need is multiplied by bgwriter_lru_multiplier to arrive at an estimate of the number of buffers that will be needed during the next round. Dirty buffers are written until there are that many clean, reusable buffers available. (However, no more than bgwriter_lru_maxpages buffers will be written per round.) Thus, a setting of 1.0 represents a “just in time” policy of writing exactly the number of buffers predicted to be needed. Larger values provide some cushion against spikes in demand, while smaller values intentionally leave writes to be done by server processes. The default is 2.0. This parameter can only be set in the postgresql.conf file or on the server command line.

bgwriter_flush_after (integer)

Whenever more than this amount of data has been written by the background writer, attempt to force the OS to issue these writes to the underlying storage. Doing so will limit the amount of dirty data in the kernel's page cache, reducing the likelihood of stalls when an fsync is issued at the end of a checkpoint, or when the OS writes data back in larger batches in the background. Often that will result in greatly reduced transaction latency, but there also are some cases, especially with workloads that are bigger than shared_buffers, but smaller than the OS's page cache, where performance might degrade. This setting may have no effect on some platforms. If this value is specified without units, it is taken as blocks, that is BLCKSZ bytes, typically 8kB. The valid range is between 0, which disables forced writeback, and 2MB. The default is 512kB on Linux, 0 elsewhere. (If BLCKSZ is not 8kB, the maximum value scales proportionally to it.) This parameter can only be set in the postgresql.conf file or on the server command line.

Smaller values of bgwriter_lru_maxpages and bgwriter_lru_multiplier reduce the extra I/O load caused by the background writer, but make it more likely that server processes will have to issue writes for themselves, delaying interactive queries.

18.4.6. Asynchronous Behavior

backend_flush_after (integer)

Whenever more than this amount of data has been written by a single backend, attempt to force the OS to issue these writes to the underlying storage. Doing so will limit the amount of dirty data in the kernel's page cache, reducing the likelihood of stalls when an fsync is issued at the end of a checkpoint, or when the OS writes data back in larger batches in the background. Often that will result in greatly reduced transaction latency, but there also are some cases, especially with workloads that are bigger than shared_buffers, but smaller than the OS's page cache, where performance might degrade. This setting may have no effect on some platforms. If this value is specified without units, it is taken as blocks, that is BLCKSZ bytes, typically 8kB. The valid range is between 0, which disables forced writeback, and 2MB. The default is 0, i.e., no forced writeback. (If BLCKSZ is not 8kB, the maximum value scales proportionally to it.)
effective_io_concurrency (integer)

Sets the number of concurrent disk I/O operations that Postgres Pro expects can be executed simultaneously. Raising this value will increase the number of I/O operations that any individual Postgres Pro session attempts to initiate in parallel. The allowed range is 1 to 1000, or zero to disable issuance of asynchronous I/O requests. Currently, this setting only affects bitmap heap scans.

For magnetic drives, a good starting point for this setting is the number of separate drives comprising a RAID 0 stripe or RAID 1 mirror being used for the database. (For RAID 5 the parity drive should not be counted.) However, if the database is often busy with multiple queries issued in concurrent sessions, lower values may be sufficient to keep the disk array busy. A value higher than needed to keep the disks busy will only result in extra CPU overhead. SSDs and other memory-based storage can often process many concurrent requests, so the best value might be in the hundreds.

Asynchronous I/O depends on an effective posix_fadvise function, which some operating systems lack. If the function is not present then setting this parameter to anything but zero will result in an error. On some operating systems (e.g., Solaris), the function is present but does not actually do anything.

The default is 1 on supported systems, otherwise 0. This value can be overridden for tables in a particular tablespace by setting the tablespace parameter of the same name (see ALTER TABLESPACE).

maintenance_io_concurrency (integer)

Similar to effective_io_concurrency, but used for maintenance work that is done on behalf of many client sessions.

The default is 10 on supported systems, otherwise 0. This value can be overridden for tables in a particular tablespace by setting the tablespace parameter of the same name (see ALTER TABLESPACE).

max_worker_processes (integer)

Sets the maximum number of background processes that the system can support. This parameter can only be set at server start. The default is 8.

When running a standby server, you must set this parameter to the same or higher value than on the primary server. Otherwise, queries will not be allowed in the standby server.

When changing this value, consider also adjusting max_parallel_workers, max_parallel_maintenance_workers, and max_parallel_workers_per_gather.

max_parallel_workers_per_gather (integer)

Sets the maximum number of workers that can be started by a single Gather or Gather Merge node. Parallel workers are taken from the pool of processes established by max_worker_processes, limited by max_parallel_workers. Note that the requested number of workers may not actually be available at run time. If this occurs, the plan will run with fewer workers than expected, which may be inefficient. The default value is 2. Setting this value to 0 disables parallel query execution.

Note that parallel queries may consume very substantially more resources than non-parallel queries, because each worker process is a completely separate process which has roughly the same impact on the system as an additional user session. This should be taken into account when choosing a value for this setting, as well as when configuring other settings that control resource utilization, such as work_mem. Resource limits such as work_mem are applied individually to each worker, which means the total utilization may be much higher across all processes than it would normally be for any single process. For example, a parallel query using 4 workers may use up to 5 times as much CPU time, memory, I/O bandwidth, and so forth as a query which uses no workers at all.

For more information on parallel query, see Chapter 15.
max_parallel_maintenance_workers (integer)

Sets the maximum number of parallel workers that can be started by a single utility command. Currently, the parallel utility commands that support the use of parallel workers are `CREATE INDEX` only when building a B-tree index, and `VACUUM` without `FULL` option. Parallel workers are taken from the pool of processes established by `max_worker_processes`, limited by `max_parallel_workers`. Note that the requested number of workers may not actually be available at run time. If this occurs, the utility operation will run with fewer workers than expected. The default value is 2. Setting this value to 0 disables the use of parallel workers by utility commands.

Note that parallel utility commands should not consume substantially more memory than equivalent non-parallel operations. This strategy differs from that of parallel query, where resource limits generally apply per worker process. Parallel utility commands treat the resource limit `maintenance_work_mem` as a limit to be applied to the entire utility command, regardless of the number of parallel worker processes. However, parallel utility commands may still consume substantially more CPU resources and I/O bandwidth.

max_parallel_workers (integer)

Sets the maximum number of workers that the system can support for parallel operations. The default value is 8. When increasing or decreasing this value, consider also adjusting `max_parallel_maintenance_workers` and `max_parallel_workers_per_gather`. Also, note that a setting for this value which is higher than `max_worker_processes` will have no effect, since parallel workers are taken from the pool of worker processes established by that setting.

parallel_leader_participation (boolean)

Allows the leader process to execute the query plan under `Gather` and `Gather Merge` nodes instead of waiting for worker processes. The default is `on`. Setting this value to `off` reduces the likelihood that workers will become blocked because the leader is not reading tuples fast enough, but requires the leader process to wait for worker processes to start up before the first tuples can be produced. The degree to which the leader can help or hinder performance depends on the plan type, number of workers and query duration.

old_snapshot_threshold (integer)

Sets the minimum amount of time that a query snapshot can be used without risk of a “snapshot too old” error occurring when using the snapshot. Data that has been dead for longer than this threshold is allowed to be vacuumed away. This can help prevent bloat in the face of snapshots which remain in use for a long time. To prevent incorrect results due to cleanup of data which would otherwise be visible to the snapshot, an error is generated when the snapshot is older than this threshold and the snapshot is used to read a page which has been modified since the snapshot was built.

If this value is specified without units, it is taken as minutes. A value of `-1` (the default) disables this feature, effectively setting the snapshot age limit to infinity. This parameter can only be set at server start.

Useful values for production work probably range from a small number of hours to a few days. Small values (such as `0` or `1min`) are only allowed because they may sometimes be useful for testing. While a setting as high as `60d` is allowed, please note that in many workloads extreme bloat or transaction ID wraparound may occur in much shorter time frames.

When this feature is enabled, freed space at the end of a relation cannot be released to the operating system, since that could remove information needed to detect the “snapshot too old” condition. All space allocated to a relation remains associated with that relation for reuse only within that relation unless explicitly freed (for example, with `VACUUM FULL`).

This setting does not attempt to guarantee that an error will be generated under any particular circumstances. In fact, if the correct results can be generated from (for example) a cursor which has materialized a result set, no error will be generated even if the underlying rows in the referenced table have been vacuumed away. Some tables cannot safely be vacuumed early, and so will not be
affected by this setting, such as system catalogs. For such tables this setting will neither reduce bloat nor create a possibility of a “snapshot too old” error on scanning.

18.5. Write Ahead Log

For additional information on tuning these settings, see Section 28.5.

18.5.1. Settings

wal_level (enum)

wal_level determines how much information is written to the WAL. The default value is replica, which writes enough data to support WAL archiving and replication, including running read-only queries on a standby server. minimal removes all logging except the information required to recover from a crash or immediate shutdown. Finally, logical adds information necessary to support logical decoding. Each level includes the information logged at all lower levels. This parameter can only be set at server start.

In minimal level, no information is logged for permanent relations for the remainder of a transaction that creates or rewrites them. This can make operations much faster (see Section 14.4.7). Operations that initiate this optimization include:

ALTER ... SET TABLESPACE
CLUSTER
CREATE TABLE
REFRESH MATERIALIZED VIEW
(without CONCURRENTLY)
REINDEX
TRUNCATE

But minimal WAL does not contain enough information to reconstruct the data from a base backup and the WAL logs, so replica or higher must be used to enable WAL archiving (archive_mode) and streaming replication. Note that changing wal_level to minimal makes any base backups taken before unavailable for archive recovery and standby server, which may lead to data loss.

In logical level, the same information is logged as with replica, plus information needed to allow extracting logical change sets from the WAL. Using a level of logical will increase the WAL volume, particularly if many tables are configured for REPLICA IDENTITY FULL and many UPDATE and DELETE statements are executed.

In releases prior to 9.6, this parameter also allowed the values archive and hot_standby. These are still accepted but mapped to replica.

fsync (boolean)

If this parameter is on, the Postgres Pro server will try to make sure that updates are physically written to disk, by issuing fsync() system calls or various equivalent methods (see wal_sync_method). This ensures that the database cluster can recover to a consistent state after an operating system or hardware crash.

While turning off fsync is often a performance benefit, this can result in unrecoverable data corruption in the event of a power failure or system crash. Thus it is only advisable to turn off fsync if you can easily recreate your entire database from external data.

Examples of safe circumstances for turning off fsync include the initial loading of a new database cluster from a backup file, using a database cluster for processing a batch of data after which the database will be thrown away and recreated, or for a read-only database clone which gets recreated frequently and is not used for failover. High quality hardware alone is not a sufficient justification for turning off fsync.

For reliable recovery when changing fsync off to on, it is necessary to force all modified buffers in the kernel to durable storage. This can be done while the cluster is shutdown or while fsync is on by running initdb --sync-only, running sync, unmounting the file system, or rebooting the server.
In many situations, turning off `synchronous_commit` for noncritical transactions can provide much of the potential performance benefit of turning off `fsync`, without the attendant risks of data corruption.

`fsync` can only be set in the `postgresql.conf` file or on the server command line. If you turn this parameter off, also consider turning off `full_page_writes`.

`synchronous_commit` (enum)

Specifies how much WAL processing must complete before the database server returns a “success” indication to the client. Valid values are `remote_apply`, `on` (the default), `remote_write`, `local`, and `off`.

If `synchronous_standby_names` is empty, the only meaningful settings are `on` and `off`; `remote_apply`, `remote_write` and `local` all provide the same local synchronization level as `on`. The local behavior of all non-off modes is to wait for local flush of WAL to disk. In `off` mode, there is no waiting, so there can be a delay between when success is reported to the client and when the transaction is later guaranteed to be safe against a server crash. (The maximum delay is three times `wal_writer_delay`.) Unlike `fsync`, setting this parameter to `off` does not create any risk of database inconsistency: an operating system or database crash might result in some recent allegedly-committed transactions being lost, but the database state will be just the same as if those transactions had been aborted cleanly. So, turning `synchronous_commit` off can be a useful alternative when performance is more important than exact certainty about the durability of a transaction. For more discussion see Section 28.4.

If `synchronous_standby_names` is non-empty, `synchronous_commit` also controls whether transaction commits will wait for their WAL records to be processed on the standby server(s).

When set to `remote_apply`, commits will wait until replies from the current synchronous standby(s) indicate they have received the commit record of the transaction and applied it, so that it has become visible to queries on the standby(s), and also written to durable storage on the standbys. This will cause much larger commit delays than previous settings since it waits for WAL replay. When set to `on`, commits wait until replies from the current synchronous standby(s) indicate they have received the commit record of the transaction and flushed it to durable storage. This ensures the transaction will not be lost unless both the primary and all synchronous standbys suffer corruption of their database storage. When set to `remote_write`, commits will wait until replies from the current synchronous standby(s) indicate they have received the commit record of the transaction and written it to their file systems. This setting ensures data preservation if a standby instance of Postgres Pro crashes, but not if the standby suffers an operating-system-level crash because the data has not necessarily reached durable storage on the standby. The setting `local` causes commits to wait for local flush to disk, but not for replication. This is usually not desirable when synchronous replication is in use, but is provided for completeness.

This parameter can be changed at any time; the behavior for any one transaction is determined by the setting in effect when it commits. It is therefore possible, and useful, to have some transactions commit synchronously and others asynchronously. For example, to make a single multistatement transaction commit asynchronously when the default is the opposite, issue `SET LOCAL synchronous_commit TO OFF` within the transaction.

Table 18.1 summarizes the capabilities of the `synchronous_commit` settings.

<table>

**wal_sync_method (enum)**

Method used for forcing WAL updates out to disk. If fsync is off then this setting is irrelevant, since WAL file updates will not be forced out at all. Possible values are:

- open_datsasync (write WAL files with open( ) option O_DSYNC)
- fdatasync (call fdatasync( ) at each commit)
- fsync (call fsync( ) at each commit)
- fsync_writethrough (call fsync( ) at each commit, forcing write-through of any disk write cache)
- open_sync (write WAL files with open( ) option O_SYNC)

The open_* options also use O_DIRECT if available. Not all of these choices are available on all platforms. The default is the first method in the above list that is supported by the platform, except that fdatasync is the default on Linux and FreeBSD. The default is not necessarily ideal; it might be necessary to change this setting or other aspects of your system configuration in order to create a crash-safe configuration or achieve optimal performance. These aspects are discussed in Section 28.1. This parameter can only be set in the postgresql.conf file or on the server command line.

**full_page_writes (boolean)**

When this parameter is on, the Postgres Pro server writes the entire content of each disk page to WAL during the first modification of that page after a checkpoint. This is needed because a page write that is in process during an operating system crash might be only partially completed, leading to an on-disk page that contains a mix of old and new data. The row-level change data normally stored in WAL will not be enough to completely restore such a page during post-crash recovery. Storing the full page image guarantees that the page can be correctly restored, but at the price of increasing the amount of data that must be written to WAL. (Because WAL replay always starts from a checkpoint, it is sufficient to do this during the first change of each page after a checkpoint. Therefore, one way to reduce the cost of full-page writes is to increase the checkpoint interval parameters.)

Turning this parameter off speeds normal operation, but might lead to either unrecoverable data corruption, or silent data corruption, after a system failure. The risks are similar to turning off fsync, though smaller, and it should be turned off only based on the same circumstances recommended for that parameter.

Turning off this parameter does not affect use of WAL archiving for point-in-time recovery (PITR) (see Section 24.3).

This parameter can only be set in the postgresql.conf file or on the server command line. The default is on.

**wal_log_hints (boolean)**

When this parameter is on, the Postgres Pro server writes the entire content of each disk page to WAL during the first modification of that page after a checkpoint, even for non-critical modifications of so-called hint bits.

If data checksums are enabled, hint bit updates are always WAL-logged and this setting is ignored. You can use this setting to test how much extra WAL-logging would occur if your database had data checksums enabled.
**Server Configuration**

This parameter can only be set at server start. The default value is off.

**wal_compression (boolean)**

When this parameter is on, the Postgres Pro server compresses full page images written to WAL when full page writes is on or during a base backup. A compressed page image will be decompressed during WAL replay. The default value is off. Only superusers can change this setting.

Turning this parameter on can reduce the WAL volume without increasing the risk of unrecoverable data corruption, but at the cost of some extra CPU spent on the compression during WAL logging and on the decompression during WAL replay.

**wal_init_zero (boolean)**

If set to on (the default), this option causes new WAL files to be filled with zeroes. On some file systems, this ensures that space is allocated before we need to write WAL records. However, Copy-On-Write (COW) file systems may not benefit from this technique, so the option is given to skip the unnecessary work. If set to off, only the final byte is written when the file is created so that it has the expected size.

**wal_recycle (boolean)**

If set to on (the default), this option causes WAL files to be recycled by renaming them, avoiding the need to create new ones. On COW file systems, it may be faster to create new ones, so the option is given to disable this behavior.

**wal_buffers (integer)**

The amount of shared memory used for WAL data that has not yet been written to disk. The default setting of -1 selects a size equal to 1/32nd (about 3%) of shared_buffers, but not less than 64kB nor more than the size of one WAL segment, typically 16MB. This value can be set manually if the automatic choice is too large or too small, but any positive value less than 32kB will be treated as 32kB. If this value is specified without units, it is taken as WAL blocks, that is XLOG_BLCKSZ bytes, typically 8kB. This parameter can only be set at server start.

The contents of the WAL buffers are written out to disk at every transaction commit, so extremely large values are unlikely to provide a significant benefit. However, setting this value to at least a few megabytes can improve write performance on a busy server where many clients are committing at once. The auto-tuning selected by the default setting of -1 should give reasonable results in most cases.

**wal_writer_delay (integer)**

Specifies how often the WAL writer flushes WAL, in time terms. After flushing WAL the writer sleeps for the length of time given by wal_writer_delay, unless woken up sooner by an asynchronously committing transaction. If the last flush happened less than wal_writer_delay ago and less than wal_writer_flush_after worth of WAL has been produced since, then WAL is only written to the operating system, not flushed to disk. If this value is specified without units, it is taken as milliseconds. The default value is 200 milliseconds (200ms). Note that on many systems, the effective resolution of sleep delays is 10 milliseconds; setting wal_writer_delay to a value that is not a multiple of 10 might have the same results as setting it to the next higher multiple of 10. This parameter can only be set in the postgresql.conf file or on the server command line.

**wal_writer_flush_after (integer)**

Specifies how often the WAL writer flushes WAL, in volume terms. If the last flush happened less than wal_writer_delay ago and less than wal_writer_flush_after worth of WAL has been produced since, then WAL is only written to the operating system, not flushed to disk. If wal_writer_flush_after is set to 0 then WAL data is always flushed immediately. If this value is specified without units, it is taken as WAL blocks, that is XLOG_BLCKSZ bytes, typically 8kB. The default is 1MB. This parameter can only be set in the postgresql.conf file or on the server command line.
Server Configuration

**wal_skip_threshold (integer)**

When `wal_level` is minimal and a transaction commits after creating or rewriting a permanent relation, this setting determines how to persist the new data. If the data is smaller than this setting, write it to the WAL log; otherwise, use an fsync of affected files. Depending on the properties of your storage, raising or lowering this value might help if such commits are slowing concurrent transactions. If this value is specified without units, it is taken as kilobytes. The default is two megabytes (2MB).

**commit_delay (integer)**

Setting `commit_delay` adds a time delay before a WAL flush is initiated. This can improve group commit throughput by allowing a larger number of transactions to commit via a single WAL flush, if system load is high enough that additional transactions become ready to commit within the given interval. However, it also increases latency by up to the `commit_delay` for each WAL flush. Because the delay is just wasted if no other transactions become ready to commit, a delay is only performed if at least `commit_siblings` other transactions are active when a flush is about to be initiated. Also, no delays are performed if `fsync` is disabled. If this value is specified without units, it is taken as microseconds. The default `commit_delay` is zero (no delay). Only superusers can change this setting.

In PostgreSQL releases prior to 9.3, `commit_delay` behaved differently and was much less effective: it affected only commits, rather than all WAL flushes, and waited for the entire configured delay even if the WAL flush was completed sooner. Beginning in PostgreSQL 9.3, the first process that becomes ready to flush waits for the configured interval, while subsequent processes wait only until the leader completes the flush operation.

**commit_siblings (integer)**

Minimum number of concurrent open transactions to require before performing the `commit_delay` delay. A larger value makes it more probable that at least one other transaction will become ready to commit during the delay interval. The default is five transactions.

### 18.5.2. Checkpoints

**checkpoint_timeout (integer)**

Maximum time between automatic WAL checkpoints. If this value is specified without units, it is taken as seconds. The valid range is between 30 seconds and one day. The default is five minutes (5min). Increasing this parameter can increase the amount of time needed for crash recovery. This parameter can only be set in the `postgresql.conf` file or on the server command line.

**checkpoint_completion_target (floating point)**

Specifies the target of checkpoint completion, as a fraction of total time between checkpoints. The default is 0.9, which spreads the checkpoint across almost all of the available interval, providing fairly consistent I/O load while also leaving some time for checkpoint completion overhead. Reducing this parameter is not recommended because it causes the checkpoint to complete faster. This results in a higher rate of I/O during the checkpoint followed by a period of less I/O between the checkpoint completion and the next scheduled checkpoint. This parameter can only be set in the `postgresql.conf` file or on the server command line.

**checkpoint_flush_after (integer)**

Whenever more than this amount of data has been written while performing a checkpoint, attempt to force the OS to issue these writes to the underlying storage. Doing so will limit the amount of dirty data in the kernel's page cache, reducing the likelihood of stalls when an `fsync` is issued at the end of the checkpoint, or when the OS writes data back in larger batches in the background. Often that will result in greatly reduced transaction latency, but there also are some cases, especially with workloads that are bigger than `shared_buffers`, but smaller than the OS's page cache, where performance might degrade. This setting may have no effect on some platforms. If this value is specified without units, it is taken as blocks, that is `BLCKSZ` bytes, typically 8kB. The valid range is between 0, which disables forced writeback, and 2MB. The default is 256kB on Linux, 0 elsewhere. (If
BLCKSZ is not 8kB, the default and maximum values scale proportionally to it.) This parameter can only be set in the `postgresql.conf` file or on the server command line.

### checkpoint_warning (integer)

Write a message to the server log if checkpoints caused by the filling of WAL segment files happen closer together than this amount of time (which suggests that `max_wal_size` ought to be raised). If this value is specified without units, it is taken as seconds. The default is 30 seconds (30s). Zero disables the warning. No warnings will be generated if `checkpoint_timeout` is less than `checkpoint_warning`. This parameter can only be set in the `postgresql.conf` file or on the server command line.

### max_wal_size (integer)

Maximum size to let the WAL grow during automatic checkpoints. This is a soft limit; WAL size can exceed `max_wal_size` under special circumstances, such as heavy load, a failing `archive_command`, or a high `wal_keep_size` setting. If this value is specified without units, it is taken as megabytes. The default is 1 GB. Increasing this parameter can increase the amount of time needed for crash recovery. This parameter can only be set in the `postgresql.conf` file or on the server command line.

### min_wal_size (integer)

As long as WAL disk usage stays below this setting, old WAL files are always recycled for future use at a checkpoint, rather than removed. This can be used to ensure that enough WAL space is reserved to handle spikes in WAL usage, for example when running large batch jobs. If this value is specified without units, it is taken as megabytes. The default is 80 MB. This parameter can only be set in the `postgresql.conf` file or on the server command line.

### 18.5.3. Archiving

#### archive_mode (enum)

When `archive_mode` is enabled, completed WAL segments are sent to archive storage by setting `archive_command`. In addition to `off`, to disable, there are two modes: `on`, and `always`. During normal operation, there is no difference between the two modes, but when set to `always` the WAL archiver is enabled also during archive recovery or standby mode. In `always` mode, all files restored from the archive or streamed with streaming replication will be archived (again). See Section 25.2.9 for details.

`archive_mode` and `archive_command` are separate variables so that `archive_command` can be changed without leaving archiving mode. This parameter can only be set at server start. `archive_mode` cannot be enabled when `wal_level` is set to `minimal`.

#### archive_command (string)

The local shell command to execute to archive a completed WAL file segment. Any `%p` in the string is replaced by the path name of the file to archive, and any `%f` is replaced by only the file name. (The path name is relative to the working directory of the server, i.e., the cluster's data directory.) Use `%` to embed an actual `%` character in the command. It is important for the command to return a zero exit status only if it succeeds. For more information see Section 24.3.1.

This parameter can only be set in the `postgresql.conf` file or on the server command line. It is ignored unless `archive_mode` was enabled at server start. If `archive_command` is an empty string (the default) while `archive_mode` is enabled, WAL archiving is temporarily disabled, but the server continues to accumulate WAL segment files in the expectation that a command will soon be provided. Setting `archive_command` to a command that does nothing but return true, e.g., `/bin/true` (REM on Windows), effectively disables archiving, but also breaks the chain of WAL files needed for archive recovery, so it should only be used in unusual circumstances.

#### archive_timeout (integer)

The `archive_command` is only invoked for completed WAL segments. Hence, if your server generates little WAL traffic (or has slack periods where it does so), there could be a long delay between the
completion of a transaction and its safe recording in archive storage. To limit how old unarchived data can be, you can set `archive_timeout` to force the server to switch to a new WAL segment file periodically. When this parameter is greater than zero, the server will switch to a new segment file whenever this amount of time has elapsed since the last segment file switch, and there has been any database activity, including a single checkpoint (checkpoints are skipped if there is no database activity). Note that archived files that are closed early due to a forced switch are still the same length as completely full files. Therefore, it is unwise to use a very short `archive_timeout` — it will bloat your archive storage. `archive_timeout` settings of a minute or so are usually reasonable. You should consider using streaming replication, instead of archiving, if you want data to be copied off the primary server more quickly than that. If this value is specified without units, it is taken as seconds. This parameter can only be set in the `postgresql.conf` file or on the server command line.

### 18.5.4. Archive Recovery

This section describes the settings that apply only for the duration of the recovery. They must be reset for any subsequent recovery you wish to perform.

“Recovery” covers using the server as a standby or for executing a targeted recovery. Typically, standby mode would be used to provide high availability and/or read scalability, whereas a targeted recovery is used to recover from data loss.

To start the server in standby mode, create a file called `standby.signal` in the data directory. The server will enter recovery and will not stop recovery when the end of archived WAL is reached, but will keep trying to continue recovery by connecting to the sending server as specified by the `primary_conninfo` setting and/or by fetching new WAL segments using `restore_command`. For this mode, the parameters from this section and Section 18.6.3 are of interest. Parameters from Section 18.5.5 will also be applied but are typically not useful in this mode.

To start the server in targeted recovery mode, create a file called `recovery.signal` in the data directory. If both `standby.signal` and `recovery.signal` files are created, standby mode takes precedence. Targeted recovery mode ends when the archived WAL is fully replayed, or when `recovery_target` is reached. In this mode, the parameters from both this section and Section 18.5.5 will be used.

**restore_command** (string)

The local shell command to execute to retrieve an archived segment of the WAL file series. This parameter is required for archive recovery, but optional for streaming replication. Any `%f` in the string is replaced by the name of the file to retrieve from the archive, and any `%p` is replaced by the copy destination path name on the server. (The path name is relative to the current working directory, i.e., the cluster's data directory.) Any `%r` is replaced by the name of the file containing the last valid restart point. That is the earliest file that must be kept to allow a restore to be restartable, so this information can be used to truncate the archive to just the minimum required to support restarting from the current restore. `%r` is typically only used by warm-standby configurations (see Section 25.2). Write `%%` to embed an actual `%` character.

It is important for the command to return a zero exit status only if it succeeds. The command will be asked for file names that are not present in the archive; it must return nonzero when so asked.

Examples:

```
restore_command = 'cp /mnt/server/archivedir/%f "%p"'
restore_command = 'copy "C:\server\archivedir\%f" "%p"'  # Windows
```

An exception is that if the command was terminated by a signal (other than SIGTERM, which is used as part of a database server shutdown) or an error by the shell (such as command not found), then recovery will abort and the server will not start up.

**archive_cleanup_command** (string)

This optional parameter specifies a shell command that will be executed at every restartpoint. The purpose of `archive_cleanup_command` is to provide a mechanism for cleaning up old archived WAL files that are no longer needed by the standby server. Any `%r` is replaced by the name of the
file containing the last valid restart point. That is the earliest file that must be kept to allow a
restart to be restartable, and so all files earlier than %r may be safely removed. This information
can be used to truncate the archive to just the minimum required to support restart from the
current restore. The pg_archivecleanup module is often used in archive_cleanup_command for
single-standby configurations, for example:

archive_cleanup_command = 'pg_archivecleanup /mnt/server/archivedir %r'

Note however that if multiple standby servers are restoring from the same archive directory, you
will need to ensure that you do not delete WAL files until they are no longer needed by any of the
servers. archive_cleanup_command would typically be used in a warm-standby configuration (see
Section 25.2). Write %r to embed an actual % character in the command.

If the command returns a nonzero exit status then a warning log message will be written. An
exception is that if the command was terminated by a signal or an error by the shell (such as command
not found), a fatal error will be raised.

This parameter can only be set in the postgresql.conf file or on the server command line.

recovery_end_command (string)

This parameter specifies a shell command that will be executed once only at the end of recovery.
This parameter is optional. The purpose of the recovery_end_command is to provide a mechanism for
cleanup following replication or recovery. Any %r is replaced by the name of the file containing the
last valid restart point, like in archive_cleanup_command.

If the command returns a nonzero exit status then a warning log message will be written and the
database will proceed to start up anyway. An exception is that if the command was terminated by
a signal or an error by the shell (such as command not found), the database will not proceed with
startup.

This parameter can only be set in the postgresql.conf file or on the server command line.

18.5.5. Recovery Target

By default, recovery will recover to the end of the WAL log. The following parameters can be
used to specify an earlier stopping point. At most one of recovery_target, recovery_target_lsn,
recovery_target_name, recovery_target_time, or recovery_target_xid can be used; if more than
one of these is specified in the configuration file, an error will be raised. These parameters can only be
set at server start.

recovery_target = 'immediate'

This parameter specifies that recovery should end as soon as a consistent state is reached, i.e., as
early as possible. When restoring from an online backup, this means the point where taking the
backup ended.

Technically, this is a string parameter, but 'immediate' is currently the only allowed value.

recovery_target_name (string)

This parameter specifies the named restore point (created with pg_create_restore_point()) to
which recovery will proceed.

recovery_target_time (timestamp)

This parameter specifies the time stamp up to which recovery will proceed. The precise stopping
point is also influenced by recovery_target_inclusive.

The value of this parameter is a time stamp in the same format accepted by the timestamp
with time zone data type, except that you cannot use a time zone abbreviation (unless the
timezone_abbreviations variable has been set earlier in the configuration file). Preferred style is to
use a numeric offset from UTC, or you can write a full time zone name, e.g., Europe/Helsinki not
EEST.
recovery_target_xid (string)

This parameter specifies the transaction ID up to which recovery will proceed. Keep in mind that while transaction IDs are assigned sequentially at transaction start, transactions can complete in a different numeric order. The transactions that will be recovered are those that committed before (and optionally including) the specified one. The precise stopping point is also influenced by recovery_target_inclusive.

recovery_target_lsn (pg_lsn)

This parameter specifies the LSN of the write-ahead log location up to which recovery will proceed. The precise stopping point is also influenced by recovery_target_inclusive. This parameter is parsed using the system data type pg_lsn.

The following options further specify the recovery target, and affect what happens when the target is reached:

recovery_target_inclusive (boolean)

Specifies whether to stop just after the specified recovery target (on), or just before the recovery target (off). Applies when recovery_target_lsn, recovery_target_time, or recovery_target_xid is specified. This setting controls whether transactions having exactly the target WAL location (LSN), commit time, or transaction ID, respectively, will be included in the recovery. Default is on.

recovery_target_timeline (string)

Specifies recovering into a particular timeline. The value can be a numeric timeline ID or a special value. The value current recovers along the same timeline that was current when the base backup was taken. The value latest recovers to the latest timeline found in the archive, which is useful in a standby server. latest is the default.

You usually only need to set this parameter in complex re-recovery situations, where you need to return to a state that itself was reached after a point-in-time recovery. See Section 24.3.5 for discussion.

recovery_target_action (enum)

Specifies what action the server should take once the recovery target is reached. The default is pause, which means recovery will be paused. promote means the recovery process will finish and the server will start to accept connections. Finally shutdown will stop the server after reaching the recovery target.

The intended use of the pause setting is to allow queries to be executed against the database to check if this recovery target is the most desirable point for recovery. The paused state can be resumed by using pg_wal_replay_resume() (see Table 9.89), which then causes recovery to end. If this recovery target is not the desired stopping point, then shut down the server, change the recovery target settings to a later target and restart to continue recovery.

The shutdown setting is useful to have the instance ready at the exact replay point desired. The instance will still be able to replay more WAL records (and in fact will have to replay WAL records since the last checkpoint next time it is started).

Note that because recovery.signal will not be removed when recovery_target_action is set to shutdown, any subsequent start will end with immediate shutdown unless the configuration is changed or the recovery.signal file is removed manually.

This setting has no effect if no recovery target is set. If hot_standby is not enabled, a setting of pause will act the same as shutdown. If the recovery target is reached while a promotion is ongoing, a setting of pause will act the same as promote.

In any case, if a recovery target is configured but the archive recovery ends before the target is reached, the server will shut down with a fatal error.
18.6. Replication

These settings control the behavior of the built-in streaming replication feature (see Section 25.2.5). Servers will be either a primary or a standby server. Primaries can send data, while standbys are always receivers of replicated data. When cascading replication (see Section 25.2.7) is used, standby servers can also be senders, as well as receivers. Parameters are mainly for sending and standby servers, though some parameters have meaning only on the primary server. Settings may vary across the cluster without problems if that is required.

18.6.1. Sending Servers

These parameters can be set on any server that is to send replication data to one or more standby servers. The primary is always a sending server, so these parameters must always be set on the primary. The role and meaning of these parameters does not change after a standby becomes the primary.

max_wal_senders (integer)

Specifies the maximum number of concurrent connections from standby servers or streaming base backup clients (i.e., the maximum number of simultaneously running WAL sender processes). The default is 10. The value 0 means replication is disabled. Abrupt disconnection of a streaming client might leave an orphaned connection slot behind until a timeout is reached, so this parameter should be set slightly higher than the maximum number of expected clients so disconnected clients can immediately reconnect. This parameter can only be set at server start. Also, wal_level must be set to replica or higher to allow connections from standby servers.

When running a standby server, you must set this parameter to the same or higher value than on the primary server. Otherwise, queries will not be allowed in the standby server.

max_replication_slots (integer)

Specifies the maximum number of replication slots (see Section 25.2.6) that the server can support. The default is 10. This parameter can only be set at server start. Setting it to a lower value than the number of currently existing replication slots will prevent the server from starting. Also, wal_level must be set to replica or higher to allow replication slots to be used.

On the subscriber side, specifies how many replication origins (see Chapter 48) can be tracked simultaneously, effectively limiting how many logical replication subscriptions can be created on the server. Setting it to a lower value than the current number of tracked replication origins (reflected in pg_replication_origin_status, not pg_replication_origin) will prevent the server from starting.

wal_keep_size (integer)

Specifies the minimum size of past log file segments kept in the pg_wal directory, in case a standby server needs to fetch them for streaming replication. If a standby server connected to the sending server falls behind by more than wal_keep_size megabytes, the sending server might remove a WAL segment still needed by the standby, in which case the replication connection will be terminated. Downstream connections will also eventually fail as a result. (However, the standby server can recover by fetching the segment from archive, if WAL archiving is in use.)

This sets only the minimum size of segments retained in pg_wal; the system might need to retain more segments for WAL archival or to recover from a checkpoint. If wal_keep_size is zero (the default), the system doesn't keep any extra segments for standby purposes, so the number of old WAL segments available to standby servers is a function of the location of the previous checkpoint and status of WAL archiving. If this value is specified without units, it is taken as megabytes. This parameter can only be set in the postgresql.conf file or on the server command line.

max_slot_wal_keep_size (integer)

Specify the maximum size of WAL files that replication slots are allowed to retain in the pg_wal directory at checkpoint time. If max_slot_wal_keep_size is -1 (the default), replication slots may retain an unlimited amount of WAL files. Otherwise, if restart_lsn of a replication slot falls behind the
Server Configuration

Current LSN by more than the given size, the standby using the slot may no longer be able to continue replication due to removal of required WAL files. You can see the WAL availability of replication slots in `pg_replication_slots`.

`wal_sender_timeout` (integer)

Terminate replication connections that are inactive for longer than this amount of time. This is useful for the sending server to detect a standby crash or network outage. If this value is specified without units, it is taken as milliseconds. The default value is 60 seconds. A value of zero disables the timeout mechanism.

With a cluster distributed across multiple geographic locations, using different values per location brings more flexibility in the cluster management. A smaller value is useful for faster failure detection with a standby having a low-latency network connection, and a larger value helps in judging better the health of a standby if located on a remote location, with a high-latency network connection.

`track_commit_timestamp` (boolean)

Record commit time of transactions. This parameter can only be set in `postgresql.conf` file or on the server command line. The default value is `off`.

18.6.2. Primary Server

These parameters can be set on the primary server that is to send replication data to one or more standby servers. Note that in addition to these parameters, `wal_level` must be set appropriately on the primary server, and optionally WAL archiving can be enabled as well (see Section 18.5.3). The values of these parameters on standby servers are irrelevant, although you may wish to set them there in preparation for the possibility of a standby becoming the primary.

`synchronous_standby_names` (string)

Specifies a list of standby servers that can support synchronous replication, as described in Section 25.2.8. There will be one or more active synchronous standbys; transactions waiting for commit will be allowed to proceed after these standby servers confirm receipt of their data. The synchronous standbys will be those whose names appear in this list, and that are both currently connected and streaming data in real-time (as shown by a state of `streaming` in the `pg_stat_replication` view). Specifying more than one synchronous standby can allow for very high availability and protection against data loss.

The name of a standby server for this purpose is the `application_name` setting of the standby, as set in the standby's connection information. In case of a physical replication standby, this should be set in the `primary_conninfo` setting; the default is the setting of `cluster_name` if set, else `walreceiver`. For logical replication, this can be set in the connection information of the subscription, and it defaults to the subscription name. For other replication stream consumers, consult their documentation.

This parameter specifies a list of standby servers using either of the following syntaxes:

```
[FIRST] num_sync ( standby_name [, ...] )
ANY num_sync ( standby_name [, ...] )
standby_name [, ...]
```

where `num_sync` is the number of synchronous standbys that transactions need to wait for replies from, and `standby_name` is the name of a standby server. `FIRST` and `ANY` specify the method to choose synchronous standbys from the listed servers.

The keyword `FIRST`, coupled with `num_sync`, specifies a priority-based synchronous replication and makes transaction commits wait until their WAL records are replicated to `num_sync` synchronous standbys chosen based on their priorities. For example, a setting of `FIRST 3 (s1, s2, s3, s4)` will cause each commit to wait for replies from three higher-priority standbys chosen from standby servers `s1`, `s2`, `s3` and `s4`. The standbys whose names appear earlier in the list are given higher priority and will be considered as synchronous. Other standby servers appearing later in this list represent potential synchronous standbys. If any of the current synchronous standbys disconnects for
whatever reason, it will be replaced immediately with the next-highest-priority standby. The keyword FIRST is optional.

The keyword ANY, coupled with num_sync, specifies a quorum-based synchronous replication and makes transaction commits wait until their WAL records are replicated to at least num_sync listed standbys. For example, a setting of ANY 3 (s1, s2, s3, s4) will cause each commit to proceed as soon as at least any three standbys of s1, s2, s3 and s4 reply.

FIRST and ANY are case-insensitive. If these keywords are used as the name of a standby server, its standby_name must be double-quoted.

The third syntax was used before Postgres Pro version 9.6 and is still supported. It's the same as the first syntax with FIRST and num_sync equal to 1. For example, FIRST 1 (s1, s2) and s1, s2 have the same meaning: either s1 or s2 is chosen as a synchronous standby.

The special entry * matches any standby name.

There is no mechanism to enforce uniqueness of standby names. In case of duplicates one of the matching standbys will be considered as higher priority, though exactly which one is indeterminate.

<table>
<thead>
<tr>
<th>Note</th>
</tr>
</thead>
<tbody>
<tr>
<td>Each standby_name should have the form of a valid SQL identifier, unless it is *. You can use double-quoting if necessary. But note that standby_names are compared to standby application names case-insensitively, whether double-quoted or not.</td>
</tr>
</tbody>
</table>

If no synchronous standby names are specified here, then synchronous replication is not enabled and transaction commits will not wait for replication. This is the default configuration. Even when synchronous replication is enabled, individual transactions can be configured not to wait for replication by setting the synchronous_commit parameter to local or off.

This parameter can only be set in the postgresql.conf file or on the server command line.

vacuum_defer_cleanup_age (integer)

Specifies the number of transactions by which VACUUM and HOT updates will defer cleanup of dead row versions. The default is zero transactions, meaning that dead row versions can be removed as soon as possible, that is, as soon as they are no longer visible to any open transaction. You may wish to set this to a non-zero value on a primary server that is supporting hot standby servers, as described in Section 25.4. This allows more time for queries on the standby to complete without incurring conflicts due to early cleanup of rows. However, since the value is measured in terms of number of write transactions occurring on the primary server, it is difficult to predict just how much additional grace time will be made available to standby queries. This parameter can only be set in the postgresql.conf file or on the server command line.

You should also consider setting hot_standby_feedback on standby server(s) as an alternative to using this parameter.

This does not prevent cleanup of dead rows which have reached the age specified by old_snapshot_threshold.

18.6.3. Standby Servers

These settings control the behavior of a standby server that is to receive replication data. Their values on the primary server are irrelevant.

primary_conninfo (string)

Specifies a connection string to be used for the standby server to connect with a sending server. This string is in the format described in Section 32.1.1. If any option is unspecified in this string, then
Server Configuration

the corresponding environment variable (see Section 32.15) is checked. If the environment variable is not set either, then defaults are used.

The connection string should specify the host name (or address) of the sending server, as well as the port number if it is not the same as the standby server's default. Also specify a user name corresponding to a suitably-privileged role on the sending server (see Section 25.2.5.1). A password needs to be provided too, if the sender demands password authentication. It can be provided in the primary_conninfo string, or in a separate ~/.pgpass file on the standby server (use replication as the database name). Do not specify a database name in the primary_conninfo string.

This parameter can only be set in the postgresql.conf file or on the server command line. If this parameter is changed while the WAL receiver process is running, that process is signaled to shut down and expected to restart with the new setting (except if primary_conninfo is an empty string). This setting has no effect if the server is not in standby mode.

primary_slot_name (string)

Optionally specifies an existing replication slot to be used when connecting to the sending server via streaming replication to control resource removal on the upstream node (see Section 25.2.6). This parameter can only be set in the postgresql.conf file or on the server command line. If this parameter is changed while the WAL receiver process is running, that process is signaled to shut down and expected to restart with the new setting. This setting has no effect if primary_conninfo is not set or the server is not in standby mode.

promote_trigger_file (string)

Specifies a trigger file whose presence ends recovery in the standby. Even if this value is not set, you can still promote the standby using pg_ctl promote or calling pg_promote(). This parameter can only be set in the postgresql.conf file or on the server command line.

hot_standby (boolean)

Specifies whether or not you can connect and run queries during recovery, as described in Section 25.4. The default value is on. This parameter can only be set at server start. It only has effect during archive recovery or in standby mode.

max_standby_archive_delay (integer)

When Hot Standby is active, this parameter determines how long the standby server should wait before canceling standby queries that conflict with about-to-be-applied WAL entries, as described in Section 25.4.2. max_standby_archive_delay applies when WAL data is being read from WAL archive (and is therefore not current). If this value is specified without units, it is taken as milliseconds. The default is 30 seconds. A value of -1 allows the standby to wait forever for conflicting queries to complete. This parameter can only be set in the postgresql.conf file or on the server command line.

Note that max_standby_archive_delay is not the same as the maximum length of time a query can run before cancellation; rather it is the maximum total time allowed to apply any one WAL segment's data. Thus, if one query has resulted in significant delay earlier in the WAL segment, subsequent conflicting queries will have much less grace time.

max_standby_streaming_delay (integer)

When Hot Standby is active, this parameter determines how long the standby server should wait before canceling standby queries that conflict with about-to-be-applied WAL entries, as described in Section 25.4.2. max_standby_streaming_delay applies when WAL data is being received via streaming replication. If this value is specified without units, it is taken as milliseconds. The default is 30 seconds. A value of -1 allows the standby to wait forever for conflicting queries to complete. This parameter can only be set in the postgresql.conf file or on the server command line.

Note that max_standby_streaming_delay is not the same as the maximum length of time a query can run before cancellation; rather it is the maximum total time allowed to apply WAL data once it has been received from the primary server. Thus, if one query has resulted in significant delay,
subsequent conflicting queries will have much less grace time until the standby server has caught up again.

`wal_receiver_create_temp_slot` (boolean)

Specifies whether the WAL receiver process should create a temporary replication slot on the remote instance when no permanent replication slot to use has been configured (using `primary_slot_name`). The default is off. This parameter can only be set in the `postgresql.conf` file or on the server command line. If this parameter is changed while the WAL receiver process is running, that process is signaled to shut down and expected to restart with the new setting.

`wal_receiver_status_interval` (integer)

Specifies the minimum frequency for the WAL receiver process on the standby to send information about replication progress to the primary or upstream standby, where it can be seen using the `pg_stat_replication` view. The standby will report the last write-ahead log location it has written, the last position it has flushed to disk, and the last position it has applied. This parameter's value is the maximum amount of time between reports. Updates are sent each time the write or flush positions change, or as often as specified by this parameter if set to a non-zero value. There are additional cases where updates are sent while ignoring this parameter; for example, when processing of the existing WAL completes or when `synchronous_commit` is set to `remote_apply`. Thus, the apply position may lag slightly behind the true position. If this value is specified without units, it is taken as seconds. The default value is 10 seconds. This parameter can only be set in the `postgresql.conf` file or on the server command line.

`hot_standby_feedback` (boolean)

Specifies whether or not a hot standby will send feedback to the primary or upstream standby about queries currently executing on the standby. This parameter can be used to eliminate query cancels caused by cleanup records, but can cause database bloat on the primary for some workloads. Feedback messages will not be sent more frequently than once per `wal_receiver_status_interval`. The default value is off. This parameter can only be set in the `postgresql.conf` file or on the server command line.

If cascaded replication is in use the feedback is passed upstream until it eventually reaches the primary. Standbys make no other use of feedback they receive other than to pass upstream.

This setting does not override the behavior of `old_snapshot_threshold` on the primary; a snapshot on the standby which exceeds the primary's age threshold can become invalid, resulting in cancellation of transactions on the standby. This is because `old_snapshot_threshold` is intended to provide an absolute limit on the time which dead rows can contribute to bloat, which would otherwise be violated because of the configuration of a standby.

`wal_receiver_timeout` (integer)

Terminate replication connections that are inactive for longer than this amount of time. This is useful for the receiving standby server to detect a primary node crash or network outage. If this value is specified without units, it is taken as milliseconds. The default value is 60 seconds. A value of zero disables the timeout mechanism. This parameter can only be set in the `postgresql.conf` file or on the server command line.

`wal_retrieve_retry_interval` (integer)

Specifies how long the standby server should wait when WAL data is not available from any sources (streaming replication, local `pg_wal` or WAL archive) before trying again to retrieve WAL data. If this value is specified without units, it is taken as milliseconds. The default value is 5 seconds. This parameter can only be set in the `postgresql.conf` file or on the server command line.

This parameter is useful in configurations where a node in recovery needs to control the amount of time to wait for new WAL data to be available. For example, in archive recovery, it is possible to make the recovery more responsive in the detection of a new WAL log file by reducing the value of this parameter. On a system with low WAL activity, increasing it reduces the amount of requests
necessary to access WAL archives, something useful for example in cloud environments where the amount of times an infrastructure is accessed is taken into account.

recovery_min_apply_delay (integer)

By default, a standby server restores WAL records from the sending server as soon as possible. It may be useful to have a time-delayed copy of the data, offering opportunities to correct data loss errors. This parameter allows you to delay recovery by a specified amount of time. For example, if you set this parameter to 5min, the standby will replay each transaction commit only when the system time on the standby is at least five minutes past the commit time reported by the primary. If this value is specified without units, it is taken as milliseconds. The default is zero, adding no delay.

It is possible that the replication delay between servers exceeds the value of this parameter, in which case no delay is added. Note that the delay is calculated between the WAL time stamp as written on primary and the current time on the standby. Delays in transfer because of network lag or cascading replication configurations may reduce the actual wait time significantly. If the system clocks on primary and standby are not synchronized, this may lead to recovery applying records earlier than expected; but that is not a major issue because useful settings of this parameter are much larger than typical time deviations between servers.

The delay occurs only on WAL records for transaction commits. Other records are replayed as quickly as possible, which is not a problem because MVCC visibility rules ensure their effects are not visible until the corresponding commit record is applied.

The delay occurs once the database in recovery has reached a consistent state, until the standby is promoted or triggered. After that the standby will end recovery without further waiting.

This parameter is intended for use with streaming replication deployments; however, if the parameter is specified it will be honored in all cases except crash recovery. hot_standby_feedback will be delayed by use of this feature which could lead to bloat on the primary; use both together with care.

**Warning**

Synchronous replication is affected by this setting when synchronous_commit is set to remote_apply; every COMMIT will need to wait to be applied.

This parameter can only be set in the `postgresql.conf` file or on the server command line.

### 18.6.4. Subscribers

These settings control the behavior of a logical replication subscriber. Their values on the publisher are irrelevant.

Note that wal_receiver_timeout, wal_receiver_status_interval and wal_retrieve_retry_interval configuration parameters affect the logical replication workers as well.

max_logical_replication_workers (int)

Specifies maximum number of logical replication workers. This includes both apply workers and table synchronization workers.

Logical replication workers are taken from the pool defined by max_worker_processes.

The default value is 4. This parameter can only be set at server start.

max_sync_workers_per_subscription (integer)

Maximum number of synchronization workers per subscription. This parameter controls the amount of parallelism of the initial data copy during the subscription initialization or when new tables are added.
Server Configuration

Currently, there can be only one synchronization worker per table. The synchronization workers are taken from the pool defined by `max_logical_replication_workers`.

The default value is 2. This parameter can only be set in the `postgresql.conf` file or on the server command line.

18.7. Query Planning

18.7.1. Planner Method Configuration

These configuration parameters provide a crude method of influencing the query plans chosen by the query optimizer. If the default plan chosen by the optimizer for a particular query is not optimal, a temporary solution is to use one of these configuration parameters to force the optimizer to choose a different plan. Better ways to improve the quality of the plans chosen by the optimizer include adjusting the planner cost constants (see Section 18.7.2), running `ANALYZE` manually, increasing the value of the `default_statistics_target` configuration parameter, and increasing the amount of statistics collected for specific columns using `ALTER TABLE SET STATISTICS`.

`enable_async_append (boolean)`

Enables or disables the query planner's use of async-aware append plan types. The default is `on`.

`enable_bitmapscan (boolean)`

Enables or disables the query planner's use of bitmap-scan plan types. The default is `on`.

`enable_gathermerge (boolean)`

Enables or disables the query planner's use of gather merge plan types. The default is `on`.

`enable_hashagg (boolean)`

Enables or disables the query planner's use of hashed aggregation plan types. The default is `on`.

`enable_hashjoin (boolean)`

Enables or disables the query planner's use of hash-join plan types. The default is `on`.

`enable_incremental_sort (boolean)`

Enables or disables the query planner's use of incremental sort steps. The default is `on`.

`enable_indexscan (boolean)`

Enables or disables the query planner's use of index-scan plan types. The default is `on`.

`enable_indexonlyscan (boolean)`

Enables or disables the query planner's use of index-only-scan plan types (see Section 11.9). The default is `on`.

`enable_material (boolean)`

Enables or disables the query planner's use of materialization. It is impossible to suppress materialization entirely, but turning this variable off prevents the planner from inserting materialize nodes except in cases where it is required for correctness. The default is `on`.

`enable_memoize (boolean)`

Enables or disables the query planner's use of memoize plans for caching results from parameterized scans inside nested-loop joins. This plan type allows scans to the underlying plans to be skipped when the results for the current parameters are already in the cache. Less commonly looked up results may be evicted from the cache when more space is required for new entries. The default is `on`.
enable_mergejoin (boolean)

Enables or disables the query planner's use of merge-join plan types. The default is on.

enable_nestloop (boolean)

Enables or disables the query planner's use of nested-loop join plans. It is impossible to suppress nested-loop joins entirely, but turning this variable off discourages the planner from using one if there are other methods available. The default is on.

enable_parallel_append (boolean)

Enables or disables the query planner's use of parallel-aware append plan types. The default is on.

enable_parallel_hash (boolean)

Enables or disables the query planner's use of hash-join plan types with parallel hash. Has no effect if hash-join plans are not also enabled. The default is on.

enable_partition_pruning (boolean)

Enables or disables the query planner's ability to eliminate a partitioned table's partitions from query plans. This also controls the planner's ability to generate query plans which allow the query executor to remove (ignore) partitions during query execution. The default is on. See Section 5.11.4 for details.

enable_partitionwise_join (boolean)

Enables or disables the query planner's use of partitionwise join, which allows a join between partitioned tables to be performed by joining the matching partitions. Partitionwise join currently applies only when the join conditions include all the partition keys, which must be of the same data type and have one-to-one matching sets of child partitions. Because partitionwise join planning can use significantly more CPU time and memory during planning, the default is off.

enable_partitionwise_aggregate (boolean)

Enables or disables the query planner's use of partitionwise grouping or aggregation, which allows grouping or aggregation on a partitioned tables performed separately for each partition. If the GROUP BY clause does not include the partition keys, only partial aggregation can be performed on a per-partition basis, and finalization must be performed later. Because partitionwise grouping or aggregation can use significantly more CPU time and memory during planning, the default is off.

enable_self_join_removal (boolean)

Enables or disables removal of self joins from query plans. Removing self joins based on unique column can significantly speed up queries without affecting the results.

Default: on

enable_compound_index_stats (boolean)

Enables or disables use of compound indexes statistics for selectivity estimation.

Default: on

enable_seqscan (boolean)

Enables or disables the query planner's use of sequential scan plan types. It is impossible to suppress sequential scans entirely, but turning this variable off discourages the planner from using one if there are other methods available. The default is on.

enable_sort (boolean)

Enables or disables the query planner's use of explicit sort steps. It is impossible to suppress explicit sorts entirely, but turning this variable off discourages the planner from using one if there are other methods available. The default is on.
enable_tidscan (boolean)

Enables or disables the query planner's use of TID scan plan types. The default is on.

18.7.2. Planner Cost Constants

The cost variables described in this section are measured on an arbitrary scale. Only their relative values matter, hence scaling them all up or down by the same factor will result in no change in the planner's choices. By default, these cost variables are based on the cost of sequential page fetches; that is, seq_page_cost is conventionally set to 1.0 and the other cost variables are set with reference to that. But you can use a different scale if you prefer, such as actual execution times in milliseconds on a particular machine.

Note

Unfortunately, there is no well-defined method for determining ideal values for the cost variables. They are best treated as averages over the entire mix of queries that a particular installation will receive. This means that changing them on the basis of just a few experiments is very risky.

seq_page_cost (floating point)

Sets the planner's estimate of the cost of a disk page fetch that is part of a series of sequential fetches. The default is 1.0. This value can be overridden for tables and indexes in a particular tablespace by setting the tablespace parameter of the same name (see ALTER TABLESPACE).

random_page_cost (floating point)

Sets the planner's estimate of the cost of a non-sequentially-fetched disk page. The default is 4.0. This value can be overridden for tables and indexes in a particular tablespace by setting the tablespace parameter of the same name (see ALTER TABLESPACE).

Reducing this value relative to seq_page_cost will cause the system to prefer index scans; raising it will make index scans look relatively more expensive. You can raise or lower both values together to change the importance of disk I/O costs relative to CPU costs, which are described by the following parameters.

Random access to mechanical disk storage is normally much more expensive than four times sequential access. However, a lower default is used (4.0) because the majority of random accesses to disk, such as indexed reads, are assumed to be in cache. The default value can be thought of as modeling random access as 40 times slower than sequential, while expecting 90% of random reads to be cached.

If you believe a 90% cache rate is an incorrect assumption for your workload, you can increase random_page_cost to better reflect the true cost of random storage reads. Correspondingly, if your data is likely to be completely in cache, such as when the database is smaller than the total server memory, decreasing random_page_cost can be appropriate. Storage that has a low random read cost relative to sequential, e.g., solid-state drives, might also be better modeled with a lower value for random_page_cost, e.g., 1.1.

Tip

Although the system will let you set random_page_cost to less than seq_page_cost, it is not physically sensible to do so. However, setting them equal makes sense if the database is entirely cached in RAM, since in that case there is no penalty for touching pages out of sequence. Also, in a heavily-cached database you should lower both values relative to the CPU parameters, since the cost of fetching a page already in RAM is much smaller than it would normally be.

cpu_tuple_cost (floating point)

Sets the planner's estimate of the cost of processing each row during a query. The default is 0.01.
Server Configuration

cpu_index_tuple_cost (floating point)
Sets the planner's estimate of the cost of processing each index entry during an index scan. The
default is 0.005.

cpu_operator_cost (floating point)
Sets the planner's estimate of the cost of processing each operator or function executed during a
query. The default is 0.0025.

parallel_setup_cost (floating point)
Sets the planner's estimate of the cost of launching parallel worker processes. The default is 1000.

parallel_tuple_cost (floating point)
Sets the planner's estimate of the cost of transferring one tuple from a parallel worker process to
another process. The default is 0.1.

min_parallel_table_scan_size (integer)
Sets the minimum amount of table data that must be scanned in order for a parallel scan to be
considered. For a parallel sequential scan, the amount of table data scanned is always equal to the
size of the table, but when indexes are used the amount of table data scanned will normally be less.
If this value is specified without units, it is taken as blocks, that is BLCKSZ bytes, typically 8kB. The
default is 8 megabytes (8MB).

min_parallel_index_scan_size (integer)
Sets the minimum amount of index data that must be scanned in order for a parallel scan to be
considered. Note that a parallel index scan typically won't touch the entire index; it is the number
of pages which the planner believes will actually be touched by the scan which is relevant. This
parameter is also used to decide whether a particular index can participate in a parallel vacuum. See
VACUUM. If this value is specified without units, it is taken as blocks, that is BLCKSZ bytes, typically
8kB. The default is 512 kilobytes (512kB).

effective_cache_size (integer)
Sets the planner's assumption about the effective size of the disk cache that is available to a single
query. This is factored into estimates of the cost of using an index; a higher value makes it more likely
index scans will be used, a lower value makes it more likely sequential scans will be used. When
setting this parameter you should consider both Postgres Pro's shared buffers and the portion of the
kernel's disk cache that will be used for Postgres Pro data files, though some data might exist in
both places. Also, take into account the expected number of concurrent queries on different tables,
since they will have to share the available space. This parameter has no effect on the size of shared
memory allocated by Postgres Pro, nor does it reserve kernel disk cache; it is used only for estimation
purposes. The system also does not assume data remains in the disk cache between queries. If this
value is specified without units, it is taken as blocks, that is BLCKSZ bytes, typically 8kB. The default
is 4 gigabytes (4GB). (If BLCKSZ is not 8kB, the default value scales proportionally to it.)

jit_above_cost (floating point)
Sets the query cost above which JIT compilation is activated, if enabled (see Chapter 30). Performing
JIT costs planning time but can accelerate query execution. Setting this to -1 disables JIT compilation.
The default is 100000.

jit_inline_above_cost (floating point)
Sets the query cost above which JIT compilation attempts to inline functions and operators. Inlining
adds planning time, but can improve execution speed. It is not meaningful to set this to less than
jit_above_cost. Setting this to -1 disables inlining. The default is 500000.

jit_optimize_above_cost (floating point)
Sets the query cost above which JIT compilation applies expensive optimizations. Such optimization
adds planning time, but can improve execution speed. It is not meaningful to set this to less than
jit_above_cost, and it is unlikely to be beneficial to set it to more than jit_inline_above_cost. Setting this to -1 disables expensive optimizations. The default is 500000.

18.7.3. Genetic Query Optimizer

The genetic query optimizer (GEQO) is an algorithm that does query planning using heuristic searching. This reduces planning time for complex queries (those joining many relations), at the cost of producing plans that are sometimes inferior to those found by the normal exhaustive-search algorithm. For more information see Chapter 56.

geqo (boolean)

Enables or disables genetic query optimization. This is on by default. It is usually best not to turn it off in production; the geqo_threshold variable provides more granular control of GEQO.

geqo_threshold (integer)

Use genetic query optimization to plan queries with at least this many FROM items involved. (Note that a FULL OUTER JOIN construct counts as only one FROM item.) The default is 12. For simpler queries it is usually best to use the regular, exhaustive-search planner, but for queries with many tables the exhaustive search takes too long, often longer than the penalty of executing a suboptimal plan. Thus, a threshold on the size of the query is a convenient way to manage use of GEQO.

geqo_effort (integer)

Controls the trade-off between planning time and query plan quality in GEQO. This variable must be an integer in the range from 1 to 10. The default value is five. Larger values increase the time spent doing query planning, but also increase the likelihood that an efficient query plan will be chosen.

geqo_effort doesn't actually do anything directly; it is only used to compute the default values for the other variables that influence GEQO behavior (described below). If you prefer, you can set the other parameters by hand instead.

geqo_pool_size (integer)

Controls the pool size used by GEQO, that is the number of individuals in the genetic population. It must be at least two, and useful values are typically 100 to 1000. If it is set to zero (the default setting) then a suitable value is chosen based on geqo_effort and the number of tables in the query.

geqo_generations (integer)

Controls the number of generations used by GEQO, that is the number of iterations of the algorithm. It must be at least one, and useful values are in the same range as the pool size. If it is set to zero (the default setting) then a suitable value is chosen based on geqo_pool_size.

geqo_selection_bias (floating point)

Controls the selection bias used by GEQO. The selection bias is the selective pressure within the population. Values can be from 1.50 to 2.00; the latter is the default.

geqo_seed (floating point)

Controls the initial value of the random number generator used by GEQO to select random paths through the join order search space. The value can range from zero (the default) to one. Varying the value changes the set of join paths explored, and may result in a better or worsen best path being found.

18.7.4. Other Planner Options

default_statistics_target (integer)

Sets the default statistics target for table columns without a column-specific target set via ALTER TABLE SET STATISTICS. Larger values increase the time needed to do ANALYZE, but might improve the quality of the planner's estimates. The default is 100. For more information on the use of statistics by the Postgres Pro query planner, refer to Section 14.2.
Server Configuration

constraint_exclusion (enum)

Controls the query planner's use of table constraints to optimize queries. The allowed values of constraint_exclusion are on (examine constraints for all tables), off (never examine constraints), and partition (examine constraints only for inheritance child tables and UNION ALL subqueries). partition is the default setting. It is often used with traditional inheritance trees to improve performance.

When this parameter allows it for a particular table, the planner compares query conditions with the table's CHECK constraints, and omits scanning tables for which the conditions contradict the constraints. For example:

```
CREATE TABLE parent(key integer, ...);
CREATE TABLE child1000(check (key between 1000 and 1999)) INHERITS(parent);
CREATE TABLE child2000(check (key between 2000 and 2999)) INHERITS(parent);
...
SELECT * FROM parent WHERE key = 2400;
```

With constraint exclusion enabled, this SELECT will not scan child1000 at all, improving performance.

Currently, constraint exclusion is enabled by default only for cases that are often used to implement table partitioning via inheritance trees. Turning it on for all tables imposes extra planning overhead that is quite noticeable on simple queries, and most often will yield no benefit for simple queries. If you have no tables that are partitioned using traditional inheritance, you might prefer to turn it off entirely. (Note that the equivalent feature for partitioned tables is controlled by a separate parameter, enable_partition_pruning.)

Refer to Section 5.11.5 for more information on using constraint exclusion to implement partitioning.

cursor_tuple_fraction (floating point)

Sets the planner's estimate of the fraction of a cursor's rows that will be retrieved. The default is 0.1. Smaller values of this setting bias the planner towards using “fast start” plans for cursors, which will retrieve the first few rows quickly while perhaps taking a long time to fetch all rows. Larger values put more emphasis on the total estimated time. At the maximum setting of 1.0, cursors are planned exactly like regular queries, considering only the total estimated time and not how soon the first rows might be delivered.

from_collapse_limit (integer)

The planner will merge sub-queries into upper queries if the resulting FROM list would have no more than this many items. Smaller values reduce planning time but might yield inferior query plans. The default is eight. For more information see Section 14.3.

Setting this value to geqo_threshold or more may trigger use of the GEQO planner, resulting in non-optimal plans. See Section 18.7.3.

jit (boolean)

Determines whether JIT compilation may be used by Postgres Pro, if available (see Chapter 30). The default is on.

join_collapse_limit (integer)

The planner will rewrite explicit JOIN constructs (except FULL JOINs) into lists of FROM items whenever a list of no more than this many items would result. Smaller values reduce planning time but might yield inferior query plans.

By default, this variable is set the same as from_collapse_limit, which is appropriate for most uses. Setting it to 1 prevents any reordering of explicit joins. Thus, the explicit join order specified in the query will be the actual order in which the relations are joined. Because the query planner does not always choose the optimal join order, advanced users can elect to temporarily set this variable to 1, and then specify the join order they desire explicitly. For more information see Section 14.3.
Server Configuration

Setting this value to `geqo_threshold` or more may trigger use of the GEQO planner, resulting in non-optimal plans. See Section 18.7.3.

`plan_cache_mode` (enum)

Prepared statements (either explicitly prepared or implicitly generated, for example by PL/pgSQL) can be executed using custom or generic plans. Custom plans are made afresh for each execution using its specific set of parameter values, while generic plans do not rely on the parameter values and can be re-used across executions. Thus, use of a generic plan saves planning time, but if the ideal plan depends strongly on the parameter values then a generic plan may be inefficient. The choice between these options is normally made automatically, but it can be overridden with `plan_cache_mode`. The allowed values are `auto` (the default), `force_custom_plan` and `force_generic_plan`. This setting is considered when a cached plan is to be executed, not when it is prepared. For more information see PREPARE.

18.8. Error Reporting and Logging

18.8.1. Where to Log

`log_destination` (string)

Postgres Pro supports several methods for logging server messages, including stderr, csvlog and syslog. On Windows, eventlog is also supported. Set this parameter to a list of desired log destinations separated by commas. The default is to log to stderr only. This parameter can only be set in the `postgresql.conf` file or on the server command line.

If csvlog is included in `log_destination`, log entries are output in “comma separated value” (CSV) format, which is convenient for loading logs into programs. See Section 18.8.4 for details. `logging_collector` must be enabled to generate CSV-format log output.

When either stderr or csvlog are included, the file `current_logfiles` is created to record the location of the log file(s) currently in use by the logging collector and the associated logging destination. This provides a convenient way to find the logs currently in use by the instance. Here is an example of this file's content:

```
stderr log/postgresql.log
csvlog log/postgresql.csv
```

`current_logfiles` is recreated when a new log file is created as an effect of rotation, and when `log_destination` is reloaded. It is removed when neither stderr nor csvlog are included in `log_destination`, and when the logging collector is disabled.

Note

On most Unix systems, you will need to alter the configuration of your system's syslog daemon in order to make use of the syslog option for `log_destination`. Postgres Pro can log to syslog facilities `LOCAL0` through `LOCAL7` (see `syslog_facility`), but the default syslog configuration on most platforms will discard all such messages. You will need to add something like:

```
local0.*    /var/log/postgresql
```

to the syslog daemon's configuration file to make it work.

On Windows, when you use the `eventlog` option for `log_destination`, you should register an event source and its library with the operating system so that the Windows Event Viewer can display event log messages cleanly. See Section 17.12 for details.

`logging_collector` (boolean)

This parameter enables the `logging collector`, which is a background process that captures log messages sent to stderr and redirects them into log files. This approach is often more useful than
logging to syslog, since some types of messages might not appear in syslog output. (One common example is dynamic-linker failure messages; another is error messages produced by scripts such as archive_command.) This parameter can only be set at server start.

**Note**

It is possible to log to stderr without using the logging collector; the log messages will just go to wherever the server's stderr is directed. However, that method is only suitable for low log volumes, since it provides no convenient way to rotate log files. Also, on some platforms not using the logging collector can result in lost or garbled log output, because multiple processes writing concurrently to the same log file can overwrite each other's output.

**Note**

The logging collector is designed to never lose messages. This means that in case of extremely high load, server processes could be blocked while trying to send additional log messages when the collector has fallen behind. In contrast, syslog prefers to drop messages if it cannot write them, which means it may fail to log some messages in such cases but it will not block the rest of the system.

log_directory (string)

When logging_collector is enabled, this parameter determines the directory in which log files will be created. It can be specified as an absolute path, or relative to the cluster data directory. This parameter can only be set in the postgresql.conf file or on the server command line. The default is log.

log_filename (string)

When logging_collector is enabled, this parameter sets the file names of the created log files. The value is treated as a strftime pattern, so %-escapes can be used to specify time-varying file names. (Note that if there are any time-zone-dependent %-escapes, the computation is done in the zone specified by log_timezone.) The supported %-escapes are similar to those listed in the Open Group's strftime specification. Note that the system's strftime is not used directly, so platform-specific (nonstandard) extensions do not work. The default is postgresql-%Y-%m-%d_%H%M%S.log.

If you specify a file name without escapes, you should plan to use a log rotation utility to avoid eventually filling the entire disk. In releases prior to 8.4, if no % escapes were present, PostgreSQL would append the epoch of the new log file's creation time, but this is no longer the case.

If CSV-format output is enabled in log_destination, .csv will be appended to the timestamped log file name to create the file name for CSV-format output. (If log_filename ends in .log, the suffix is replaced instead.)

This parameter can only be set in the postgresql.conf file or on the server command line.

log_file_mode (integer)

On Unix systems this parameter sets the permissions for log files when logging_collector is enabled. (On Microsoft Windows this parameter is ignored.) The parameter value is expected to be a numeric mode specified in the format accepted by the chmod and umask system calls. (To use the customary octal format the number must start with a 0 (zero).)

The default permissions are 0600, meaning only the server owner can read or write the log files. The other commonly useful setting is 0640, allowing members of the owner's group to read the files. Note however that to make use of such a setting, you'll need to alter log_directory to store the files.
somewhere outside the cluster data directory. In any case, it’s unwise to make the log files world-readable, since they might contain sensitive data.

This parameter can only be set in the *postgresql.conf* file or on the server command line.

**log_rotation_age** (integer)

When *logging_collector* is enabled, this parameter determines the maximum amount of time to use an individual log file, after which a new log file will be created. If this value is specified without units, it is taken as minutes. The default is 24 hours. Set to zero to disable time-based creation of new log files. This parameter can only be set in the *postgresql.conf* file or on the server command line.

**log_rotation_size** (integer)

When *logging_collector* is enabled, this parameter determines the maximum size of an individual log file. After this amount of data has been emitted into a log file, a new log file will be created. If this value is specified without units, it is taken as kilobytes. The default is 10 megabytes. Set to zero to disable size-based creation of new log files. This parameter can only be set in the *postgresql.conf* file or on the server command line.

**log_truncate_on_rotation** (boolean)

When *logging_collector* is enabled, this parameter will cause Postgres Pro to truncate (overwrite), rather than append to, any existing log file of the same name. However, truncation will occur only when a new file is being opened due to time-based rotation, not during server startup or size-based rotation. When off, pre-existing files will be appended to in all cases. For example, using this setting in combination with a *log_filename* like *postgresql-%H.log* would result in generating twenty-four hourly log files and then cyclically overwriting them. This parameter can only be set in the *postgresql.conf* file or on the server command line.

Example: To keep 7 days of logs, one log file per day named *server_log.Mon*, *server_log.Tue*, etc, and automatically overwrite last week’s log with this week’s log, set *log_filename* to *server_log.%a*, *log_truncate_on_rotation* to on, and *log_rotation_age* to 1440.

Example: To keep 24 hours of logs, one log file per hour, but also rotate sooner if the log file size exceeds 1GB, set *log_filename* to *server_log.%H%M*, *log_truncate_on_rotation* to on, *log_rotation_age* to 60, and *log_rotation_size* to 1000000. Including %M in *log_filename* allows any size-driven rotations that might occur to select a file name different from the hour’s initial file name.

**syslog_facility** (enum)

When logging to syslog is enabled, this parameter determines the syslog “facility” to be used. You can choose from LOCAL0, LOCAL1, LOCAL2, LOCAL3, LOCAL4, LOCAL5, LOCAL6, LOCAL7; the default is LOCAL0. See also the documentation of your system’s syslog daemon. This parameter can only be set in the *postgresql.conf* file or on the server command line.

**syslog_ident** (string)

When logging to syslog is enabled, this parameter determines the program name used to identify Postgres Pro messages in syslog logs. The default is *postgres*. This parameter can only be set in the *postgresql.conf* file or on the server command line.

**syslog_sequence_numbers** (boolean)

When logging to syslog and this is on (the default), then each message will be prefixed by an increasing sequence number (such as [2]). This circumvents the “--- last message repeated N times ---” suppression that many syslog implementations perform by default. In more modern syslog implementations, repeated message suppression can be configured (for example, $RepeatedMsgReduction in rsyslog), so this might not be necessary. Also, you could turn this off if you actually want to suppress repeated messages.
This parameter can only be set in the `postgresql.conf` file or on the server command line.

**syslog_split_messages (boolean)**

When logging to syslog is enabled, this parameter determines how messages are delivered to syslog. When on (the default), messages are split by lines, and long lines are split so that they will fit into 1024 bytes, which is a typical size limit for traditional syslog implementations. When off, Postgres Pro server log messages are delivered to the syslog service as is, and it is up to the syslog service to cope with the potentially bulky messages.

If syslog is ultimately logging to a text file, then the effect will be the same either way, and it is best to leave the setting on, since most syslog implementations either cannot handle large messages or would need to be specially configured to handle them. But if syslog is ultimately writing into some other medium, it might be necessary or more useful to keep messages logically together.

This parameter can only be set in the `postgresql.conf` file or on the server command line.

**event_source (string)**

When logging to event log is enabled, this parameter determines the program name used to identify Postgres Pro messages in the log. The default is `Postgres Pro`. This parameter can only be set in the `postgresql.conf` file or on the server command line.

### 18.8.2. When to Log

**log_min_messages (enum)**

Controls which message levels are written to the server log. Valid values are `DEBUG5`, `DEBUG4`, `DEBUG3`, `DEBUG2`, `DEBUG1`, `INFO`, `NOTICE`, `WARNING`, `ERROR`, `LOG`, `FATAL`, and `PANIC`. Each level includes all the levels that follow it. The later the level, the fewer messages are sent to the log. The default is `WARNING`. Note that `LOG` has a different rank here than in `client_min_messages`. Only superusers can change this setting.

**log_min_error_statement (enum)**

Controls which SQL statements that cause an error condition are recorded in the server log. The current SQL statement is included in the log entry for any message of the specified severity or higher. Valid values are `DEBUG5`, `DEBUG4`, `DEBUG3`, `DEBUG2`, `DEBUG1`, `INFO`, `NOTICE`, `WARNING`, `ERROR`, `LOG`, `FATAL`, and `PANIC`. The default is `ERROR`, which means statements causing errors, log messages, fatal errors, or panics will be logged. To effectively turn off logging of failing statements, set this parameter to `PANIC`. Only superusers can change this setting.

**log_min_duration_statement (integer)**

Causes the duration of each completed statement to be logged if the statement ran for at least the specified amount of time. For example, if you set it to `250ms` then all SQL statements that run 250ms or longer will be logged. Enabling this parameter can be helpful in tracking down unoptimized queries in your applications. If this value is specified without units, it is taken as milliseconds. Setting this to zero prints all statement durations. `-1` (the default) disables logging statement durations. Only superusers can change this setting.

This overrides `log_min_duration_sample`, meaning that queries with duration exceeding this setting are not subject to sampling and are always logged.

For clients using extended query protocol, durations of the Parse, Bind, and Execute steps are logged independently.

**Note**

When using this option together with `log_statement`, the text of statements that are logged because of `log_statement` will not be repeated in the duration log message. If you are not using syslog, it is recommended that you log the PID or session ID using `log_line_prefix` so...
that you can link the statement message to the later duration message using the process ID or session ID.

log_min_duration_sample (integer)

Allows sampling the duration of completed statements that ran for at least the specified amount of time. This produces the same kind of log entries as log_min_duration_statement, but only for a subset of the executed statements, with sample rate controlled by log_statement_sample_rate. For example, if you set it to 100ms then all SQL statements that run 100ms or longer will be considered for sampling. Enabling this parameter can be helpful when the traffic is too high to log all queries. If this value is specified without units, it is taken as milliseconds. Setting this to zero samples all statement durations. -1 (the default) disables sampling statement durations. Only superusers can change this setting.

This setting has lower priority than log_min_duration_statement, meaning that statements with durations exceeding log_min_duration_statement are not subject to sampling and are always logged.

Other notes for log_min_duration_statement apply also to this setting.

log_statement_sample_rate (floating point)

Determines the fraction of statements with duration exceeding log_min_duration_sample that will be logged. Sampling is stochastic, for example 0.5 means there is statistically one chance in two that any given statement will be logged. The default is 1.0, meaning to log all sampled statements. Setting this to zero disables sampled statement-duration logging, the same as setting log_min_duration_sample to -1. Only superusers can change this setting.

log_transaction_sample_rate (floating point)

Sets the fraction of transactions whose statements are all logged, in addition to statements logged for other reasons. It applies to each new transaction regardless of its statements' durations. Sampling is stochastic, for example 0.1 means there is statistically one chance in ten that any given transaction will be logged. log_transaction_sample_rate can be helpful to construct a sample of transactions. The default is 0, meaning not to log statements from any additional transactions. Setting this to 1 logs all statements of all transactions. Only superusers can change this setting.

Note

Like all statement-logging options, this option can add significant overhead.

Table 18.2 explains the message severity levels used by Postgres Pro. If logging output is sent to syslog or Windows' eventlog, the severity levels are translated as shown in the table.

Table 18.2. Message Severity Levels

<table>
<thead>
<tr>
<th>Severity</th>
<th>Usage</th>
<th>syslog</th>
<th>eventlog</th>
</tr>
</thead>
<tbody>

### 18.8.3. What to Log

**application_name** *(string)*

The `application_name` can be any string of less than `NAMEDATALEN` characters (64 characters in a standard build). It is typically set by an application upon connection to the server. The name will be displayed in the `pg_stat_activity` view and included in CSV log entries. It can also be included in regular log entries via the `log_line_prefix` parameter. Only printable ASCII characters may be used in the `application_name` value. Other characters will be replaced with question marks (`?`).

**debug_print_parse** *(boolean)*
**debug_print_rewritten** *(boolean)*
**debug_print_plan** *(boolean)*

These parameters enable various debugging output to be emitted. When set, they print the resulting parse tree, the query rewriter output, or the execution plan for each executed query. These messages are emitted at `LOG` message level, so by default they will appear in the server log but will not be sent to the client. You can change that by adjusting `client_min_messages` and/or `log_min_messages`. These parameters are off by default.

**debug_pretty_print** *(boolean)*

When set, `debug_pretty_print` indents the messages produced by `debug_print_parse`, `debug_print_rewritten`, or `debug_print_plan`. This results in more readable but much longer output than the “compact” format used when it is off. It is on by default.

**log_autovacuum_min_duration** *(integer)*

Causes each action executed by autovacuum to be logged if it ran for at least the specified amount of time. Setting this to zero logs all autovacuum actions. `-1` (the default) disables logging autovacuum actions. If this value is specified without units, it is taken as milliseconds. For example, if you set this to `250ms` then all automatic vacuums and analyzes that run `250ms` or longer will be logged. In addition, when this parameter is set to any value other than `-1`, a message will be logged if an autovacuum action is skipped due to a conflicting lock or a concurrently dropped relation. Enabling this parameter can be helpful in tracking autovacuum activity. This parameter can only be set in the `postgresql.conf` file or on the server command line; but the setting can be overridden for individual tables by changing table storage parameters.

**log_checkpoints** *(boolean)*

Causes checkpoints and restartpoints to be logged in the server log. Some statistics are included in the log messages, including the number of buffers written and the time spent writing them. This parameter can only be set in the `postgresql.conf` file or on the server command line. The default is off.

**log_connections** *(boolean)*

Causes each attempted connection to the server to be logged, as well as successful completion of both client authentication (if necessary) and authorization. Only superusers can change this parameter at session start, and it cannot be changed at all within a session. The default is off.
Some client programs, like psql, attempt to connect twice while determining if a password is required, so duplicate “connection received” messages do not necessarily indicate a problem.

**log_disconnections** (boolean)

Causes session terminations to be logged. The log output provides information similar to `log_connections`, plus the duration of the session. Only superusers can change this parameter at session start, and it cannot be changed at all within a session. The default is **off**.

**log_duration** (boolean)

Causes the duration of every completed statement to be logged. The default is **off**. Only superusers can change this setting.

For clients using extended query protocol, durations of the Parse, Bind, and Execute steps are logged independently.

**log_error_verbosity** (enum)

Controls the amount of detail written in the server log for each message that is logged. Valid values are **TERSE**, **DEFAULT**, and **VERBOSE**, each adding more fields to displayed messages. **TERSE** excludes the logging of **DETAIL**, **HINT**, **QUERY**, and **CONTEXT** error information. **VERBOSE** output includes the **SQLSTATE** error code (see also **Appendix A**) and the source code file name, function name, and line number that generated the error. Only superusers can change this setting.

**log_hostname** (boolean)

By default, connection log messages only show the IP address of the connecting host. Turning this parameter on causes logging of the host name as well. Note that depending on your host name resolution setup this might impose a non-negligible performance penalty. This parameter can only be set in the `postgresql.conf` file or on the server command line.

**log_line_prefix** (string)

This is a printf-style string that is output at the beginning of each log line. % characters begin “escape sequences” that are replaced with status information as outlined below. Unrecognized escapes are ignored. Other characters are copied straight to the log line. Some escapes are only recognized by session processes, and will be treated as empty by background processes such as the main server process. Status information may be aligned either left or right by specifying a numeric literal after the % and before the option. A negative value will cause the status information to be padded on the right with spaces to give it a minimum width, whereas a positive value will pad on the left. Padding can be useful to aid human readability in log files.

This parameter can only be set in the `postgresql.conf` file or on the server command line. The default is ‘%m [%p] ‘ which logs a time stamp and the process ID.

<table>

<td>no</td>
</tr>
<tr>
<td>%Q</td>
<td>Query identifier of the current query. Query identifiers are not computed by default, so this field will be zero unless compute_query_id parameter is enabled or a third-party module that computes query identifiers is configured.</td>
<td>yes</td>
</tr>
<tr>
<td>%%</td>
<td>Literal %</td>
<td>no</td>
</tr>
</tbody>
</table>

The backend type corresponds to the column `backend_type` in the view `pg_stat_activity`, but additional types can appear in the log that don't show in that view.

The `%c` escape prints a quasi-unique session identifier, consisting of two 4-byte hexadecimal numbers (without leading zeros) separated by a dot. The numbers are the process start time and the process ID, so `%c` can also be used as a space saving way of printing those items. For example, to generate the session identifier from `pg_stat_activity`, use this query:

```sql
SELECT to_hex(trunc(EXTRACT(EPOCH FROM backend_start))::integer) || '.' ||
```
to_hex(pid)
FROM pg_stat_activity;

**Tip**
If you set a nonempty value for `log_line_prefix`, you should usually make its last character be a space, to provide visual separation from the rest of the log line. A punctuation character can be used too.

**Tip**
Syslog produces its own time stamp and process ID information, so you probably do not want to include those escapes if you are logging to syslog.

**Tip**
The `%q` escape is useful when including information that is only available in session (backend) context like user or database name. For example:

```
log_line_prefix = '%m [%p] %q%u@d/%a '
```

**Note**
The `%Q` escape always reports a zero identifier for lines output by `log_statement` because `log_statement` generates output before an identifier can be calculated, including invalid statements for which an identifier cannot be calculated.

`log_lock_waits (boolean)`
Controls whether a log message is produced when a session waits longer than `deadlock_timeout` to acquire a lock. This is useful in determining if lock waits are causing poor performance. The default is `off`. Only superusers can change this setting.

`log_recovery_conflict_waits (boolean)`
Controls whether a log message is produced when the startup process waits longer than `deadlock_timeout` for recovery conflicts. This is useful in determining if recovery conflicts prevent the recovery from applying WAL.

The default is `off`. This parameter can only be set in the `postgresql.conf` file or on the server command line.

`log_parameter_max_length (integer)`
If greater than zero, each bind parameter value logged with a non-error statement-logging message is trimmed to this many bytes. Zero disables logging of bind parameters for non-error statement logs. `-1` (the default) allows bind parameters to be logged in full. If this value is specified without units, it is taken as bytes. Only superusers can change this setting.

This setting only affects log messages printed as a result of `log_statement`, `log_duration`, and related settings. Non-zero values of this setting add some overhead, particularly if parameters are sent in binary form, since then conversion to text is required.
Server Configuration

log_parameter_max_length_on_error (integer)

If greater than zero, each bind parameter value reported in error messages is trimmed to this many bytes. Zero (the default) disables including bind parameters in error messages. -1 allows bind parameters to be printed in full. If this value is specified without units, it is taken as bytes.

Non-zero values of this setting add overhead, as PostgreSQL will need to store textual representations of parameter values in memory at the start of each statement, whether or not an error eventually occurs. The overhead is greater when bind parameters are sent in binary form than when they are sent as text, since the former case requires data conversion while the latter only requires copying the string.

log_statement (enum)

Controls which SQL statements are logged. Valid values are none (off), ddl, mod, and all (all statements). ddl logs all data definition statements, such as CREATE, ALTER, and DROP statements. mod logs all ddl statements, plus data-modifying statements such as INSERT, UPDATE, DELETE, TRUNCATE, and COPY FROM, PREPARE, EXECUTE, and EXPLAIN ANALYZE statements are also logged if their contained command is of an appropriate type. For clients using extended query protocol, logging occurs when an Execute message is received, and values of the Bind parameters are included (with any embedded single-quote marks doubled).

The default is none. Only superusers can change this setting.

Note

Statements that contain simple syntax errors are not logged even by the log_statement = all setting, because the log message is emitted only after basic parsing has been done to determine the statement type. In the case of extended query protocol, this setting likewise does not log statements that fail before the Execute phase (i.e., during parse analysis or planning). Set log_min_error_statement to ERROR (or lower) to log such statements.

log_replication_commands (boolean)

Causes each replication command to be logged in the server log. See Section 51.4 for more information about replication command. The default value is off. Only superusers can change this setting.

log_temp_files (integer)

Controls logging of temporary file names and sizes. Temporary files can be created for sorts, hashes, and temporary query results. If enabled by this setting, a log entry is emitted for each temporary file when it is deleted. A value of zero logs all temporary file information, while positive values log only files whose size is greater than or equal to the specified amount of data. If this value is specified without units, it is taken as kilobytes. The default setting is -1, which disables such logging. Only superusers can change this setting.

log_timezone (string)

Sets the time zone used for timestamps written in the server log. Unlike TimeZone, this value is cluster-wide, so that all sessions will report timestamps consistently. The built-in default is GMT, but that is typically overridden in postgresql.conf; initdb will install a setting there corresponding to its system environment. See Section 8.5.3 for more information. This parameter can only be set in the postgresql.conf file or on the server command line.

18.8.4. Using CSV-Format Log Output

Including csvlog in the log_destination list provides a convenient way to import log files into a database table. This option emits log lines in comma-separated-values (CSV) format, with these columns:
time stamp with milliseconds, user name, database name, process ID, client host:port number, session ID, per-session line number, command tag, session start time, virtual transaction ID, regular transaction ID, error severity, SQLSTATE code, error message, error message detail, hint, internal query that led to the error (if any), character count of the error position therein, error context, user query that led to the error (if any and enabled by log_min_error_statement), character count of the error position therein, location of the error in the Postgres Pro source code (if log_error_verbosity is set to verbose), application name, backend type, process ID of parallel group leader, and query id. Here is a sample table definition for storing CSV-format log output:

```
CREATE TABLE postgres_log
(
    log_time timestamp(3) with time zone,
    user_name text,
    database_name text,
    process_id integer,
    connection_from text,
    session_id text,
    session_line_num bigint,
    command_tag text,
    session_start_time timestamp with time zone,
    virtual_transaction_id text,
    transaction_id bigint,
    error_severity text,
    sql_state_code text,
    message text,
    detail text,
    hint text,
    internal_query text,
    internal_query_pos integer,
    context text,
    query text,
    query_pos integer,
    location text,
    application_name text,
    backend_type text,
    leader_pid integer,
    query_id bigint,
    PRIMARY KEY (session_id, session_line_num)
);
```

to import a log file into this table, use the COPY FROM command:

```
COPY postgres_log FROM '/full/path/to/logfile.csv' WITH csv;
```

It is also possible to access the file as a foreign table, using the supplied file_fdw module.

There are a few things you need to do to simplify importing CSV log files:

1. Set log_filename and log_rotation_age to provide a consistent, predictable naming scheme for your log files. This lets you predict what the file name will be and know when an individual log file is complete and therefore ready to be imported.

2. Set log_rotation_size to 0 to disable size-based log rotation, as it makes the log file name difficult to predict.

3. Set log_truncate_on_rotation to on so that old log data isn't mixed with the new in the same file.

4. The table definition above includes a primary key specification. This is useful to protect against accidentally importing the same information twice. The COPY command commits all of the data it imports at one time, so any error will cause the entire import to fail. If you import a partial log file and later import the file again when it is complete, the primary key violation will cause the import
Server Configuration

to fail. Wait until the log is complete and closed before importing. This procedure will also protect against accidentally importing a partial line that hasn't been completely written, which would also cause COPY to fail.

18.8.5. Process Title

These settings control how process titles of server processes are modified. Process titles are typically viewed using programs like ps or, on Windows, Process Explorer. See Section 26.1 for details.

cluster_name (string)
Sets a name that identifies this database cluster (instance) for various purposes. The cluster name appears in the process title for all server processes in this cluster. Moreover, it is the default application name for a standby connection (see synchronous_standby_names.)

The name can be any string of less than NAMEDATALEN characters (64 characters in a standard build). Only printable ASCII characters may be used in the cluster_name value. Other characters will be replaced with question marks (?). No name is shown if this parameter is set to the empty string ‘’ (which is the default). This parameter can only be set at server start.

update_process_title (boolean)
Enables updating of the process title every time a new SQL command is received by the server. This setting defaults to on on most platforms, but it defaults to off on Windows due to that platform's larger overhead for updating the process title. Only superusers can change this setting.

18.9. Run-time Statistics

18.9.1. Query and Index Statistics Collector

These parameters control server-wide statistics collection features. When statistics collection is enabled, the data that is produced can be accessed via the pg_stat and pg_statio family of system views. Refer to Chapter 26 for more information.

track_activities (boolean)
Enables the collection of information on the currently executing command of each session, along with its identifier and the time when that command began execution. This parameter is on by default. Note that even when enabled, this information is not visible to all users, only to superusers and the user owning the session being reported on, so it should not represent a security risk. Only superusers can change this setting.

track_activity_query_size (integer)
Specifies the amount of memory reserved to store the text of the currently executing command for each active session, for the pg_stat_activity.query field. If this value is specified without units, it is taken as bytes. The default value is 1024 bytes. This parameter can only be set at server start.

track_counts (boolean)
Enables collection of statistics on database activity. This parameter is on by default, because the autovacuum daemon needs the collected information. Only superusers can change this setting.

track_io_timing (boolean)
Enables timing of database I/O calls. This parameter is off by default, as it will repeatedly query the operating system for the current time, which may cause significant overhead on some platforms. You can use the pg_test_timing tool to measure the overhead of timing on your system. I/O timing information is displayed in pg_stat_database, in the output of EXPLAIN when the BUFFERS option is used, by autovacuum for auto-vacuums and auto-analyzes, when log_autovacuum_min_duration is set and by pg_stat_statements. Only superusers can change this setting.
track_wal_io_timing (boolean)

Enables timing of WAL I/O calls. This parameter is off by default, as it will repeatedly query the operating system for the current time, which may cause significant overhead on some platforms. You can use the pg_test_timing tool to measure the overhead of timing on your system. I/O timing information is displayed in pg_stat_wal. Only superusers can change this setting.

track_functions (enum)

Enables tracking of function call counts and time used. Specify pl to track only procedural-language functions, all to also track SQL and C language functions. The default is none, which disables function statistics tracking. Only superusers can change this setting.

Note

SQL-language functions that are simple enough to be “inlined” into the calling query will not be tracked, regardless of this setting.

stats_temp_directory (string)

Sets the directory to store temporary statistics data in. This can be a path relative to the data directory or an absolute path. The default is pg_stat_tmp. Pointing this at a RAM-based file system will decrease physical I/O requirements and can lead to improved performance. This parameter can only be set in the postgresql.conf file or on the server command line.

18.9.2. Statistics Monitoring

compute_query_id (enum)

Enables in-core computation of a query identifier. Query identifiers can be displayed in the pg_stat_activity view, using EXPLAIN, or emitted in the log if configured via the log_line_prefix parameter. The pg_stat_statements extension also requires a query identifier to be computed. Note that an external module can alternatively be used if the in-core query identifier computation method is not acceptable. In this case, in-core computation must be always disabled. Valid values are off (always disabled), on (always enabled) and auto, which lets modules such as pg_stat_statements automatically enable it. The default is auto.

Note

To ensure that only one query identifier is calculated and displayed, extensions that calculate query identifiers should throw an error if a query identifier has already been computed.

log_statement_stats (boolean)
log_parser_stats (boolean)
log_planner_stats (boolean)
log_executor_stats (boolean)

For each query, output performance statistics of the respective module to the server log. This is a crude profiling instrument, similar to the Unix getrusage() operating system facility. log_statement_stats reports total statement statistics, while the others report per-module statistics. log_statement_stats cannot be enabled together with any of the per-module options. All of these options are disabled by default. Only superusers can change these settings.

18.10. Automatic Vacuuming

These settings control the behavior of the autovacuum feature. Refer to Section 23.1.6 for more information. Note that many of these settings can be overridden on a per-table basis; see Storage Parameters.
Server Configuration

autovacuum (boolean)
Controls whether the server should run the autovacuum launcher daemon. This is on by default; however, track_counts must also be enabled for autovacuum to work. This parameter can only be set in the `postgresql.conf` file or on the server command line; however, autovacuuming can be disabled for individual tables by changing table storage parameters.

Note that even when this parameter is disabled, the system will launch autovacuum processes if necessary to prevent transaction ID wraparound. See Section 23.1.5 for more information.

autovacuum_max_workers (integer)
Specifies the maximum number of autovacuum processes (other than the autovacuum launcher) that may be running at any one time. The default is three. This parameter can only be set at server start.

autovacuum_naptime (integer)
Specifies the minimum delay between autovacuum runs on any given database. In each round the daemon examines the database and issues VACUUM and ANALYZE commands as needed for tables in that database. If this value is specified without units, it is taken as seconds. The default is one minute (1min). This parameter can only be set in the `postgresql.conf` file or on the server command line.

autovacuum_vacuum_threshold (integer)
Specifies the minimum number of updated or deleted tuples needed to trigger a VACUUM in any one table. The default is 50 tuples. This parameter can only be set in the `postgresql.conf` file or on the server command line; but the setting can be overridden for individual tables by changing table storage parameters.

autovacuum_vacuum_insert_threshold (integer)
Specifies the number of inserted tuples needed to trigger a VACUUM in any one table. The default is 1000 tuples. If -1 is specified, autovacuum will not trigger a VACUUM operation on any tables based on the number of inserts. This parameter can only be set in the `postgresql.conf` file or on the server command line; but the setting can be overridden for individual tables by changing table storage parameters.

autovacuum_analyze_threshold (integer)
Specifies the minimum number of inserted, updated or deleted tuples needed to trigger an ANALYZE in any one table. The default is 50 tuples. This parameter can only be set in the `postgresql.conf` file or on the server command line; but the setting can be overridden for individual tables by changing table storage parameters.

autovacuum_vacuum_scale_factor (floating point)
Specifies a fraction of the table size to add to `autovacuum_vacuum_threshold` when deciding whether to trigger a VACUUM. The default is 0.2 (20% of table size). This parameter can only be set in the `postgresql.conf` file or on the server command line; but the setting can be overridden for individual tables by changing table storage parameters.

autovacuum_vacuum_insert_scale_factor (floating point)
Specifies a fraction of the table size to add to `autovacuum_vacuum_insert_threshold` when deciding whether to trigger a VACUUM. The default is 0.2 (20% of table size). This parameter can only be set in the `postgresql.conf` file or on the server command line; but the setting can be overridden for individual tables by changing table storage parameters.

autovacuum_analyze_scale_factor (floating point)
Specifies a fraction of the table size to add to `autovacuum_analyze_threshold` when deciding whether to trigger an ANALYZE. The default is 0.1 (10% of table size). This parameter can only be set in the `postgresql.conf` file or on the server command line; but the setting can be overridden for individual tables by changing table storage parameters.
Server Configuration

autovacuum_freeze_max_age (integer)

Specifies the maximum age (in transactions) that a table's `pg_class.relrofrozenxid` field can attain before a VACUUM operation is forced to prevent transaction ID wraparound within the table. Note that the system will launch autovacuum processes to prevent wraparound even when autovacuum is otherwise disabled.

Vacuum also allows removal of old files from the `pg_xact` subdirectory, which is why the default is a relatively low 200 million transactions. This parameter can only be set at server start, but the setting can be reduced for individual tables by changing table storage parameters. For more information see Section 23.1.5.

autovacuum_multixact_freeze_max_age (integer)

Specifies the maximum age (in multixacts) that a table's `pg_class.relminmxid` field can attain before a VACUUM operation is forced to prevent multixact ID wraparound within the table. Note that the system will launch autovacuum processes to prevent wraparound even when autovacuum is otherwise disabled.

Vacuuming multixacts also allows removal of old files from the `pg_multixact/members` and `pg_multixact/offsets` subdirectories, which is why the default is a relatively low 400 million multixacts. This parameter can only be set at server start, but the setting can be reduced for individual tables by changing table storage parameters. For more information see Section 23.1.5.1.

autovacuum_vacuum_cost_delay (floating point)

Specifies the cost delay value that will be used in automatic VACUUM operations. If -1 is specified, the regular vacuum_cost_delay value will be used. If this value is specified without units, it is taken as milliseconds. The default value is 2 milliseconds. This parameter can only be set in the `postgresql.conf` file or on the server command line; but the setting can be overridden for individual tables by changing table storage parameters.

autovacuum_vacuum_cost_limit (integer)

Specifies the cost limit value that will be used in automatic VACUUM operations. If -1 is specified (which is the default), the regular vacuum_cost_limit value will be used. Note that the value is distributed proportionally among the running autovacuum workers, if there is more than one, so that the sum of the limits for each worker does not exceed the value of this variable. This parameter can only be set in the `postgresql.conf` file or on the server command line; but the setting can be overridden for individual tables by changing table storage parameters.

18.11. Client Connection Defaults

18.11.1. Statement Behavior

client_min_messages (enum)

Controls which message levels are sent to the client. Valid values are DEBUG5, DEBUG4, DEBUG3, DEBUG2, DEBUG1, LOG, NOTICE, WARNING, and ERROR. Each level includes all the levels that follow it. The later the level, the fewer messages are sent. The default is NOTICE. Note that LOG has a different rank here than in log_min_messages.

INFO level messages are always sent to the client.

search_path (string)

This variable specifies the order in which schemas are searched when an object (table, data type, function, etc.) is referenced by a simple name with no schema specified. When there are objects of identical names in different schemas, the one found first in the search path is used. An object that is not in any of the schemas in the search path can only be referenced by specifying its containing schema with a qualified (dotted) name.
Server Configuration

The value for `search_path` must be a comma-separated list of schema names. Any name that is not an existing schema, or is a schema for which the user does not have `USAGE` permission, is silently ignored.

If one of the list items is the special name `$user`, then the schema having the name returned by `CURRENT_USER` is substituted, if there is such a schema and the user has `USAGE` permission for it. (If not, `$user` is ignored.)

The system catalog schema, `pg_catalog`, is always searched, whether it is mentioned in the path or not. If it is mentioned in the path then it will be searched in the specified order. If `pg_catalog` is not in the path then it will be searched before searching any of the path items.

Likewise, the current session’s temporary-table schema, `pg_temp_nnn`, is always searched if it exists. It can be explicitly listed in the path by using the alias `pg_temp`. If it is not listed in the path then it is searched first (even before `pg_catalog`). However, the temporary schema is only searched for relation (table, view, sequence, etc) and data type names. It is never searched for function or operator names.

When objects are created without specifying a particular target schema, they will be placed in the first valid schema named in `search_path`. An error is reported if the search path is empty.

The default value for this parameter is "$user", `public`. This setting supports shared use of a database (where no users have private schemas, and all share use of `public`), private per-user schemas, and combinations of these. Other effects can be obtained by altering the default search path setting, either globally or per-user.

For more information on schema handling, see Section 5.9. In particular, the default configuration is suitable only when the database has a single user or a few mutually-trusting users.

The current effective value of the search path can be examined via the SQL function `current_schemas` (see Section 9.26). This is not quite the same as examining the value of `search_path`, since `current_schemas` shows how the items appearing in `search_path` were resolved.

`row_security` (boolean)

This variable controls whether to raise an error in lieu of applying a row security policy. When set to `on`, policies apply normally. When set to `off`, queries fail which would otherwise apply at least one policy. The default is `on`. Change to `off` where limited row visibility could cause incorrect results; for example, `pg_dump` makes that change by default. This variable has no effect on roles which bypass every row security policy, to wit, superusers and roles with the `BYPASSRLS` attribute.

For more information on row security policies, see CREATE POLICY.

`default_table_access_method` (string)

This parameter specifies the default table access method to use when creating tables or materialized views if the `CREATE` command does not explicitly specify an access method, or when `SELECT ... INTO` is used, which does not allow to specify a table access method. The default is `heap`.

`default_tablespace` (string)

This variable specifies the default tablespace in which to create objects (tables and indexes) when a `CREATE` command does not explicitly specify a tablespace.

The value is either the name of a tablespace, or an empty string to specify using the default tablespace of the current database. If the value does not match the name of any existing tablespace, Postgres Pro will automatically use the default tablespace of the current database. If a nondefault tablespace is specified, the user must have `CREATE` privilege for it, or creation attempts will fail.

This variable is not used for temporary tables; for them, `temp_tablespaces` is consulted instead.
This variable is also not used when creating databases. By default, a new database inherits its tablespace setting from the template database it is copied from.

If this parameter is set to a value other than the empty string when a partitioned table is created, the partitioned table’s tablespace will be set to that value, which will be used as the default tablespace for partitions created in the future, even if default_tablespace has changed since then.

For more information on tablespaces, see Section 21.6.

default_toast_compression (enum)
This variable sets the default TOAST compression method for values of compressible columns. (This can be overridden for individual columns by setting the COMPRESS column option in CREATE TABLE or ALTER TABLE.) The supported compression methods are pglz and (if PostgreSQL was compiled with --with-lz4) lz4. The default is pglz.

temp_tablespaces (string)
This variable specifies tablespaces in which to create temporary objects (temp tables and indexes on temp tables) when a CREATE command does not explicitly specify a tablespace. Temporary files for purposes such as sorting large data sets are also created in these tablespaces.

The value is a list of names of tablespaces. When there is more than one name in the list, Postgres Pro chooses a random member of the list each time a temporary object is to be created; except that within a transaction, successively created temporary objects are placed in successive tablespaces from the list. If the selected element of the list is an empty string, Postgres Pro will automatically use the default tablespace of the current database instead.

When temp_tablespaces is set interactively, specifying a nonexistent tablespace is an error, as is specifying a tablespace for which the user does not have CREATE privilege. However, when using a previously set value, nonexistent tablespaces are ignored, as are tablespaces for which the user lacks CREATE privilege. In particular, this rule applies when using a value set in postgresql.conf.

The default value is an empty string, which results in all temporary objects being created in the default tablespace of the current database.

See also default_tablespace.

check_function_bodies (boolean)
This parameter is normally on. When set to off, it disables validation of the routine body string during CREATE FUNCTION and CREATE PROCEDURE. Disabling validation avoids side effects of the validation process, in particular preventing false positives due to problems such as forward references. Set this parameter to off before loading functions on behalf of other users; pg_dump does so automatically.

default_transaction_isolation (enum)
Each SQL transaction has an isolation level, which can be either “read uncommitted”, “read committed”, “repeatable read”, or “serializable”. This parameter controls the default isolation level of each new transaction. The default is “read committed”.

Consult Chapter 13 and SET TRANSACTION for more information.

default_transaction_read_only (boolean)
A read-only SQL transaction cannot alter non-temporary tables. This parameter controls the default read-only status of each new transaction. The default is off (read/write).

Consult SET TRANSACTION for more information.

default_transaction_deferrable (boolean)
When running at the serializable isolation level, a deferrable read-only SQL transaction may be delayed before it is allowed to proceed. However, once it begins executing it does not incur any of
the overhead required to ensure serializability; so serialization code will have no reason to force it to abort because of concurrent updates, making this option suitable for long-running read-only transactions.

This parameter controls the default deferrable status of each new transaction. It currently has no effect on read-write transactions or those operating at isolation levels lower than serializable. The default is off.

Consult SET TRANSACTION for more information.

```
transaction_isolation (enum)
```

This parameter reflects the current transaction's isolation level. At the beginning of each transaction, it is set to the current value of default_transaction_isolation. Any subsequent attempt to change it is equivalent to a SET TRANSACTION command.

```
transaction_read_only (boolean)
```

This parameter reflects the current transaction's read-only status. At the beginning of each transaction, it is set to the current value of default_transaction_read_only. Any subsequent attempt to change it is equivalent to a SET TRANSACTION command.

```
transaction_deferrable (boolean)
```

This parameter reflects the current transaction's deferrability status. At the beginning of each transaction, it is set to the current value of default_transaction_deferrable. Any subsequent attempt to change it is equivalent to a SET TRANSACTION command.

```
session_replication_role (enum)
```

Controls firing of replication-related triggers and rules for the current session. Setting this variable requires superuser privilege and results in discarding any previously cached query plans. Possible values are origin (the default), replica and local.

The intended use of this setting is that logical replication systems set it to replica when they are applying replicated changes. The effect of that will be that triggers and rules (that have not been altered from their default configuration) will not fire on the replica. See the ALTER TABLE clauses ENABLE TRIGGER and ENABLE RULE for more information.

Postgres Pro treats the settings origin and local the same internally. Third-party replication systems may use these two values for their internal purposes, for example using local to designate a session whose changes should not be replicated.

Since foreign keys are implemented as triggers, setting this parameter to replica also disables all foreign key checks, which can leave data in an inconsistent state if improperly used.

```
statement_timeout (integer)
```

Abort any statement that takes more than the specified amount of time. If log_min_error_statement is set to ERROR or lower, the statement that timed out will also be logged. If this value is specified without units, it is taken as milliseconds. A value of zero (the default) disables the timeout.

The timeout is measured from the time a command arrives at the server until it is completed by the server. If multiple SQL statements appear in a single simple-Query message, the timeout is applied to each statement separately. (PostgreSQL versions before 13 usually treated the timeout as applying to the whole query string.) In extended query protocol, the timeout starts running when any query-related message (Parse, Bind, Execute, Describe) arrives, and it is canceled by completion of an Execute or Sync message.

Setting statement_timeout in postgresql.conf is not recommended because it would affect all sessions.
Server Configuration

lock_timeout (integer)

Abort any statement that waits longer than the specified amount of time while attempting to acquire a lock on a table, index, row, or other database object. The time limit applies separately to each lock acquisition attempt. The limit applies both to explicit locking requests (such as LOCK TABLE, or SELECT FOR UPDATE without NOWAIT) and to implicitly-acquired locks. If this value is specified without units, it is taken as milliseconds. A value of zero (the default) disables the timeout.

Unlike statement_timeout, this timeout can only occur while waiting for locks. Note that if statement_timeout is nonzero, it is rather pointless to set lock_timeout to the same or larger value, since the statement timeout would always trigger first. If log_min_error_statement is set to ERROR or lower, the statement that timed out will be logged.

Setting lock_timeout in postgresql.conf is not recommended because it would affect all sessions.

idle_in_transaction_session_timeout (integer)

Terminate any session that has been idle (that is, waiting for a client query) within an open transaction for longer than the specified amount of time. If this value is specified without units, it is taken as milliseconds. A value of zero (the default) disables the timeout.

This option can be used to ensure that idle sessions do not hold locks for an unreasonable amount of time. Even when no significant locks are held, an open transaction prevents vacuuming away recently-dead tuples that may be visible only to this transaction; so remaining idle for a long time can contribute to table bloat. See Section 23.1 for more details.

idle_session_timeout (integer)

Terminate any session that has been idle (that is, waiting for a client query), but not within an open transaction, for longer than the specified amount of time. If this value is specified without units, it is taken as milliseconds. A value of zero (the default) disables the timeout.

Unlike the case with an open transaction, an idle session without a transaction imposes no large costs on the server, so there is less need to enable this timeout than idle_in_transaction_session_timeout.

Be wary of enforcing this timeout on connections made through connection-pooling software or other middleware, as such a layer may not react well to unexpected connection closure. It may be helpful to enable this timeout only for interactive sessions, perhaps by applying it only to particular users.

vacuum_freeze_table_age (integer)

VACUUM performs an aggressive scan if the table's pg_class.relrofrozenxid field has reached the age specified by this setting. An aggressive scan differs from a regular VACUUM in that it visits every page that might contain unfrozen XIDs or MXIDs, not just those that might contain dead tuples. The default is 150 million transactions. Although users can set this value anywhere from zero to two billion, VACUUM will silently limit the effective value to 95% of autovacuum_freeze_max_age, so that a periodic manual VACUUM has a chance to run before an anti-wraparound autovacuum is launched for the table. For more information see Section 23.1.5.

vacuum_freeze_min_age (integer)

Specifies the cutoff age (in transactions) that VACUUM should use to decide whether to freeze row versions while scanning a table. The default is 50 million transactions. Although users can set this value anywhere from zero to one billion, VACUUM will silently limit the effective value to half the value of autovacuum_freeze_max_age, so that there is not an unreasonably short time between forced autovacuums. For more information see Section 23.1.5.

vacuum_failsafe_age (integer)

Specifies the maximum age (in transactions) that a table's pg_class.relrofrozenxid field can attain before VACUUM takes extraordinary measures to avoid system-wide transaction ID wraparound failure.
This is VACUUM's strategy of last resort. The failsafe typically triggers when an autovacuum to prevent transaction ID wraparound has already been running for some time, though it's possible for the failsafe to trigger during any VACUUM.

When the failsafe is triggered, any cost-based delay that is in effect will no longer be applied, and further non-essential maintenance tasks (such as index vacuuming) are bypassed.

The default is 1.6 billion transactions. Although users can set this value anywhere from zero to 2.1 billion, VACUUM will silently adjust the effective value to no less than 105% of autovacuum_freeze_max_age.

vacuum_multixact_freeze_table_age (integer)

VACUUM performs an aggressive scan if the table's pg_class.relminmxid field has reached the age specified by this setting. An aggressive scan differs from a regular VACUUM in that it visits every page that might contain unfrozen XIDs or MXIDs, not just those that might contain dead tuples. The default is 150 million multixacts. Although users can set this value anywhere from zero to two billion, VACUUM will silently limit the effective value to 95% of autovacuum_multixact_freeze_max_age, so that a periodic manual VACUUM has a chance to run before an anti-wraparound is launched for the table. For more information see Section 23.1.5.1.

vacuum_multixact_freeze_min_age (integer)

Specifies the cutoff age (in multixacts) that VACUUM should use to decide whether to replace multixact IDs with a newer transaction ID or multixact ID while scanning a table. The default is 5 million multixacts. Although users can set this value anywhere from zero to one billion, VACUUM will silently limit the effective value to half the value of autovacuum_multixact_freeze_max_age, so that there is not an unreasonably short time between forced autovacuums. For more information see Section 23.1.5.1.

vacuum_multixact_failsafe_age (integer)

Specifies the maximum age (in multixacts) that a table's pg_class.relminmxid field can attain before VACUUM takes extraordinary measures to avoid system-wide multixact ID wraparound failure. This is VACUUM's strategy of last resort. The failsafe typically triggers when an autovacuum to prevent transaction ID wraparound has already been running for some time, though it's possible for the failsafe to trigger during any VACUUM.

When the failsafe is triggered, any cost-based delay that is in effect will no longer be applied, and further non-essential maintenance tasks (such as index vacuuming) are bypassed.

The default is 1.6 billion multixacts. Although users can set this value anywhere from zero to 2.1 billion, VACUUM will silently adjust the effective value to no less than 105% of autovacuum_multixact_freeze_max_age.

bytea_output (enum)

Sets the output format for values of type bytea. Valid values are hex (the default) and escape (the traditional Postgres Pro format). See Section 8.4 for more information. The bytea type always accepts both formats on input, regardless of this setting.

xmlbinary (enum)

Sets how binary values are to be encoded in XML. This applies for example when bytea values are converted to XML by the functions xmlRootElement or xmlForest. Possible values are base64 and hex, which are both defined in the XML Schema standard. The default is base64. For further information about XML-related functions, see Section 9.15.

The actual choice here is mostly a matter of taste, constrained only by possible restrictions in client applications. Both methods support all possible values, although the hex encoding will be somewhat larger than the base64 encoding.
Server Configuration

xml_option (enum)

Sets whether DOCUMENT or CONTENT is implicit when converting between XML and character string values. See Section 8.13 for a description of this. Valid values are DOCUMENT and CONTENT. The default is CONTENT.

According to the SQL standard, the command to set this option is

```
SET XML OPTION { DOCUMENT | CONTENT };
```

This syntax is also available in PostgreSQL.

gin_pending_list_limit (integer)

Sets the maximum size of a GIN index's pending list, which is used when fastupdate is enabled. If the list grows larger than this maximum size, it is cleaned up by moving the entries in it to the index's main GIN data structure in bulk. If this value is specified without units, it is taken as kilobytes. The default is four megabytes (4MB). This setting can be overridden for individual GIN indexes by changing index storage parameters. See Section 63.4.1 and Section 63.5 for more information.

18.11.2. Locale and Formatting

**DateStyle (string)**

Sets the display format for date and time values, as well as the rules for interpreting ambiguous date input values. For historical reasons, this variable contains two independent components: the output format specification (ISO, Postgres, SQL, or German) and the input/output specification for year/month/day ordering (DMY, MDY, or YMD). These can be set separately or together. The keywords Euro and European are synonyms for DMY; the keywords US, NonEuro, and NonEuropean are synonyms for MDY. See Section 8.5 for more information. The built-in default is ISO, MDY, but initdb will initialize the configuration file with a setting that corresponds to the behavior of the chosen lc_time locale.

**IntervalStyle (enum)**

Sets the display format for interval values. The value sql_standard will produce output matching SQL standard interval literals. The value postgres (which is the default) will produce output matching PostgreSQL releases prior to 8.4 when the DateStyle parameter was set to ISO. The value postgres_verbose will produce output matching PostgreSQL releases prior to 8.4 when the DateStyle parameter was set to non-ISO output. The value iso_8601 will produce output matching the time interval “format with designators” defined in section 4.4.3.2 of ISO 8601.

The IntervalStyle parameter also affects the interpretation of ambiguous interval input. See Section 8.5.4 for more information.

**TimeZone (string)**

Sets the time zone for displaying and interpreting time stamps. The built-in default is GMT, but that is typically overridden in postgresql.conf; initdb will install a setting there corresponding to its system environment. See Section 8.5.3 for more information.

**timezone_abbreviations (string)**

Sets the collection of time zone abbreviations that will be accepted by the server for datetime input. The default is 'Default', which is a collection that works in most of the world; there are also 'Australia' and 'India', and other collections can be defined for a particular installation. See Section B.4 for more information.

**extra_float_digits (integer)**

This parameter adjusts the number of digits used for textual output of floating-point values, including float4, float8, and geometric data types.

If the value is 1 (the default) or above, float values are output in shortest-precise format; see Section 8.1.3. The actual number of digits generated depends only on the value being output, not
on the value of this parameter. At most 17 digits are required for \texttt{float8} values, and 9 for \texttt{float4} values. This format is both fast and precise, preserving the original binary float value exactly when correctly read. For historical compatibility, values up to 3 are permitted.

If the value is zero or negative, then the output is rounded to a given decimal precision. The precision used is the standard number of digits for the type (\texttt{FLT_DIG} or \texttt{DBL_DIG} as appropriate) reduced according to the value of this parameter. (For example, specifying -1 will cause \texttt{float4} values to be output rounded to 5 significant digits, and \texttt{float8} values rounded to 14 digits.) This format is slower and does not preserve all the bits of the binary float value, but may be more human-readable.

\begin{quote}
\textbf{Note}

The meaning of this parameter, and its default value, changed in Postgres Pro 12; see Section 8.1.3 for further discussion.
\end{quote}

\begin{description}
\item[\texttt{client_encoding} (string)]

Sets the client-side encoding (character set). The default is to use the database encoding. The character sets supported by the Postgres Pro server are described in Section 22.3.1.

\item[\texttt{lc_messages} (string)]

Sets the language in which messages are displayed. Acceptable values are system-dependent; see Section 22.1 for more information. If this variable is set to the empty string (which is the default) then the value is inherited from the execution environment of the server in a system-dependent way.

On some systems, this locale category does not exist. Setting this variable will still work, but there will be no effect. Also, there is a chance that no translated messages for the desired language exist. In that case you will continue to see the English messages.

Only superusers can change this setting, because it affects the messages sent to the server log as well as to the client, and an improper value might obscure the readability of the server logs.

\item[\texttt{lc_monetary} (string)]

Sets the locale to use for formatting monetary amounts, for example with the \texttt{to_char} family of functions. Acceptable values are system-dependent; see Section 22.1 for more information. If this variable is set to the empty string (which is the default) then the value is inherited from the execution environment of the server in a system-dependent way.

\item[\texttt{lc_numeric} (string)]

Sets the locale to use for formatting numbers, for example with the \texttt{to_char} family of functions. Acceptable values are system-dependent; see Section 22.1 for more information. If this variable is set to the empty string (which is the default) then the value is inherited from the execution environment of the server in a system-dependent way.

\item[\texttt{lc_time} (string)]

Sets the locale to use for formatting dates and times, for example with the \texttt{to_char} family of functions. Acceptable values are system-dependent; see Section 22.1 for more information. If this variable is set to the empty string (which is the default) then the value is inherited from the execution environment of the server in a system-dependent way.

\item[\texttt{default_text_search_config} (string)]

Selects the text search configuration that is used by those variants of the text search functions that do not have an explicit argument specifying the configuration. See Chapter 12 for further information. The built-in default is \texttt{pg_catalog.simple}, but \texttt{initdb} will initialize the configuration file with a setting that corresponds to the chosen \texttt{lc_ctype} locale, if a configuration matching that locale can be identified.
\end{description}
18.11.3. Shared Library Preloading

Several settings are available for preloading shared libraries into the server, in order to load additional functionality or achieve performance benefits. For example, a setting of "$libdir/mylib" would cause mylib.so (or on some platforms, mylib.sl) to be preloaded from the installation's standard library directory. The differences between the settings are when they take effect and what privileges are required to change them.

Postgres Pro procedural language libraries can be preloaded in this way, typically by using the syntax "$libdir/plXXX" where XXX is pgsql, perl, tcl, or python.

Only shared libraries specifically intended to be used with Postgres Pro can be loaded this way. Every Postgres Pro-supported library has a “magic block” that is checked to guarantee compatibility. For this reason, non-Postgres Pro libraries cannot be loaded in this way. You might be able to use operating-system facilities such as LD_PRELOAD for that.

In general, refer to the documentation of a specific module for the recommended way to load that module.

local_preload_libraries (string)

This variable specifies one or more shared libraries that are to be preloaded at connection start. It contains a comma-separated list of library names, where each name is interpreted as for the LOAD command. Whitespace between entries is ignored; surround a library name with double quotes if you need to include whitespace or commas in the name. The parameter value only takes effect at the start of the connection. Subsequent changes have no effect. If a specified library is not found, the connection attempt will fail.

This option can be set by any user. Because of that, the libraries that can be loaded are restricted to those appearing in the plugins subdirectory of the installation's standard library directory. (It is the database administrator's responsibility to ensure that only “safe” libraries are installed there.) Entries in local_preload_libraries can specify this directory explicitly, for example $libdir/plugins/mylib, or just specify the library name — mylib would have the same effect as $libdir/plugins/mylib.

The intent of this feature is to allow unprivileged users to load debugging or performance-measurement libraries into specific sessions without requiring an explicit LOAD command. To that end, it would be typical to set this parameter using the PGOPTIONS environment variable on the client or by using ALTER ROLE SET.

However, unless a module is specifically designed to be used in this way by non-superusers, this is usually not the right setting to use. Look at session_preload_libraries instead.

session_preload_libraries (string)

This variable specifies one or more shared libraries that are to be preloaded at connection start. It contains a comma-separated list of library names, where each name is interpreted as for the LOAD command. Whitespace between entries is ignored; surround a library name with double quotes if you need to include whitespace or commas in the name. The parameter value only takes effect at the start of the connection. Subsequent changes have no effect. If a specified library is not found, the connection attempt will fail. Only superusers can change this setting.

The intent of this feature is to allow debugging or performance-measurement libraries to be loaded into specific sessions without an explicit LOAD command being given. For example, auto_explain could be enabled for all sessions under a given user name by setting this parameter with ALTER ROLE SET. Also, this parameter can be changed without restarting the server (but changes only take effect when a new session is started), so it is easier to add new modules this way, even if they should apply to all sessions.

Unlike shared_preload_libraries, there is no large performance advantage to loading a library at session start rather than when it is first used. There is some advantage, however, when connection pooling is used.
shared_preload_libraries (string)

This variable specifies one or more shared libraries to be preloaded at server start. It contains a comma-separated list of library names, where each name is interpreted as for the LOAD command. Whitespace between entries is ignored; surround a library name with double quotes if you need to include whitespace or commas in the name. This parameter can only be set at server start. If a specified library is not found, the server will fail to start.

Some libraries need to perform certain operations that can only take place at postmaster start, such as allocating shared memory, reserving light-weight locks, or starting background workers. Those libraries must be loaded at server start through this parameter. See the documentation of each library for details.

Other libraries can also be preloaded. By preloading a shared library, the library startup time is avoided when the library is first used. However, the time to start each new server process might increase slightly, even if that process never uses the library. So this parameter is recommended only for libraries that will be used in most sessions. Also, changing this parameter requires a server restart, so this is not the right setting to use for short-term debugging tasks, say. Use session_preload_libraries for that instead.

Note

On Windows hosts, preloading a library at server start will not reduce the time required to start each new server process; each server process will re-load all preload libraries. However, shared_preload_libraries is still useful on Windows hosts for libraries that need to perform operations at postmaster start time.

jit_provider (string)

This variable is the name of the JIT provider library to be used (see Section 30.4.2). The default is llvmjit. This parameter can only be set at server start.

If set to a non-existent library, JIT will not be available, but no error will be raised. This allows JIT support to be installed separately from the main Postgres Pro package.

18.11.4. Other Defaults

dynamic_library_path (string)

If a dynamically loadable module needs to be opened and the file name specified in the CREATE FUNCTION or LOAD command does not have a directory component (i.e., the name does not contain a slash), the system will search this path for the required file.

The value for dynamic_library_path must be a list of absolute directory paths separated by colons (or semi-colons on Windows). If a list element starts with the special string $libdir, the compiled-in Postgres Pro package library directory is substituted for $libdir; this is where the modules provided by the standard Postgres Pro distribution are installed. (Use pg_config --pkglibdir to find out the name of this directory.) For example:

dynamic_library_path = '/usr/local/lib/postgresql:/home/my_project/lib:$libdir'
or, in a Windows environment:

dynamic_library_path = 'C:\tools\postgresql;H:\my_project\lib;$libdir'

The default value for this parameter is '$libdir'. If the value is set to an empty string, the automatic path search is turned off.

This parameter can be changed at run time by superusers, but a setting done that way will only persist until the end of the client connection, so this method should be reserved for development purposes. The recommended way to set this parameter is in the postgresql.conf configuration file.
Server Configuration

gin_fuzzy_search_limit (integer)

Soft upper limit of the size of the set returned by GIN index scans. For more information see Section 63.5.

18.12. Lock Management

deadlock_timeout (integer)

This is the amount of time to wait on a lock before checking to see if there is a deadlock condition. The check for deadlock is relatively expensive, so the server doesn't run it every time it waits for a lock. We optimistically assume that deadlocks are not common in production applications and just wait on the lock for a while before checking for a deadlock. Increasing this value reduces the amount of time wasted in needless deadlock checks, but slows down reporting of real deadlock errors. If this value is specified without units, it is taken as milliseconds. The default is one second (1s), which is probably about the smallest value you would want in practice. On a heavily loaded server you might want to raise it. Ideally the setting should exceed your typical transaction time, so as to improve the odds that a lock will be released before the waiter decides to check for deadlock. Only superusers can change this setting.

When log_lock_waits is set, this parameter also determines the amount of time to wait before a log message is issued about the lock wait. If you are trying to investigate locking delays you might want to set a shorter than normal deadlock_timeout.

max_locks_per_transaction (integer)

The shared lock table tracks locks on max_locks_per_transaction * (max_connections + max_prepared_transactions) objects (e.g., tables); hence, no more than this many distinct objects can be locked at any one time. This parameter controls the average number of object locks allocated for each transaction; individual transactions can lock more objects as long as the locks of all transactions fit in the lock table. This is not the number of rows that can be locked; that value is unlimited. The default, 64, has historically proven sufficient, but you might need to raise this value if you have queries that touch many different tables in a single transaction, e.g., query of a parent table with many children. This parameter can only be set at server start.

When running a standby server, you must set this parameter to the same or higher value than on the primary server. Otherwise, queries will not be allowed in the standby server.

max_pred_locks_per_transaction (integer)

The shared predicate lock table tracks locks on max_pred_locks_per_transaction * (max_connections + max_prepared_transactions) objects (e.g., tables); hence, no more than this many distinct objects can be locked at any one time. This parameter controls the average number of object locks allocated for each transaction; individual transactions can lock more objects as long as the locks of all transactions fit in the lock table. This is not the number of rows that can be locked; that value is unlimited. The default, 64, has generally been sufficient in testing, but you might need to raise this value if you have clients that touch many different tables in a single serializable transaction. This parameter can only be set at server start.

max_pred_locks_per_relation (integer)

This controls how many pages or tuples of a single relation can be predicate-locked before the lock is promoted to covering the whole relation. Values greater than or equal to zero mean an absolute limit, while negative values mean max_pred_locks_per_transaction divided by the absolute value of this setting. The default is -2, which keeps the behavior from previous versions of Postgres Pro. This parameter can only be set in the postgresql.conf file or on the server command line.

max_pred_locks_per_page (integer)

This controls how many rows on a single page can be predicate-locked before the lock is promoted to covering the whole page. The default is 2. This parameter can only be set in the postgresql.conf file or on the server command line.
18.13. Version and Platform Compatibility

18.13.1. Previous Postgres Pro Versions

array_nulls (boolean)

This controls whether the array input parser recognizes unquoted NULL as specifying a null array element. By default, this is on, allowing array values containing null values to be entered. However, PostgreSQL versions before 8.2 did not support null values in arrays, and therefore would treat NULL as specifying a normal array element with the string value ‘NULL’. For backward compatibility with applications that require the old behavior, this variable can be turned off.

Note that it is possible to create array values containing null values even when this variable is off.

backslash_quote (enum)

This controls whether a quote mark can be represented by \ in a string literal. The preferred, SQL-standard way to represent a quote mark is by doubling it (\) but Postgres Pro has historically also accepted \\ . However, use of \\ creates security risks because in some client character set encodings, there are multibyte characters in which the last byte is numerically equivalent to ASCII \.. If client-side code does escaping incorrectly then an SQL-injection attack is possible. This risk can be prevented by making the server reject queries in which a quote mark appears to be escaped by a backslash. The allowed values of backslash_quote are on (allow \ always), off (reject always), and safe_encoding (allow only if client encoding does not allow ASCII \ within a multibyte character). safe_encoding is the default setting.

Note that in a standard-conforming string literal, \ just means \ anyway. This parameter only affects the handling of non-standard-conforming literals, including escape string syntax (E’...’).

escape_string_warning (boolean)

When on, a warning is issued if a backslash (\) appears in an ordinary string literal (’...’ syntax) and standard_conforming_strings is off. The default is on.

Applications that wish to use backslash as escape should be modified to use escape string syntax (E’...’), because the default behavior of ordinary strings is now to treat backslash as an ordinary character, per SQL standard. This variable can be enabled to help locate code that needs to be changed.

lo_compat_privileges (boolean)

In PostgreSQL releases prior to 9.0, large objects did not have access privileges and were, therefore, always readable and writable by all users. Setting this variable to on disables the new privilege checks, for compatibility with prior releases. The default is off. Only superusers can change this setting.

Setting this variable does not disable all security checks related to large objects — only those for which the default behavior has changed in PostgreSQL 9.0.

quote_all_identifiers (boolean)

When the database generates SQL, force all identifiers to be quoted, even if they are not (currently) keywords. This will affect the output of EXPLAIN as well as the results of functions like pg_get_viewdef. See also the --quote-all-identifiers option of pg_dump and pg_dumpall.

nul_byte_replacement_on_import (string)

Replace NUL bytes ‘\0’ with the specified decimal code of an ASCII character while loading data using the COPY FROM command. Such a replacement may be required when transferring data from another DBMS since Postgres Pro does not allow NUL bytes in data. The specified ASCII code must not coincide with the QUOTE and DELIMITER characters used by COPY FROM as it may cause unexpected results. The default value is ‘\0’, so no replacement occurs.
standard_conforming_strings (boolean)

This controls whether ordinary string literals ('...') treat backslashes literally, as specified in the SQL standard. Beginning in PostgreSQL 9.1, the default is on (prior releases defaulted to off). Applications can check this parameter to determine how string literals will be processed. The presence of this parameter can also be taken as an indication that the escape string syntax (E'...' is supported. Escape string syntax (Section 4.1.2.2) should be used if an application desires backslashes to be treated as escape characters.

synchronize_seqscans (boolean)

This allows sequential scans of large tables to synchronize with each other, so that concurrent scans read the same block at about the same time and hence share the I/O workload. When this is enabled, a scan might start in the middle of the table and then "wrap around" the end to cover all rows, so as to synchronize with the activity of scans already in progress. This can result in unpredictable changes in the row ordering returned by queries that have no ORDER BY clause. Setting this parameter to off ensures the pre-8.3 behavior in which a sequential scan always starts from the beginning of the table. The default is on.

18.13.2. Platform and Client Compatibility

transform_null_equals (boolean)

When on, expressions of the form expr = NULL (or NULL = expr) are treated as expr IS NULL, that is, they return true if expr evaluates to the null value, and false otherwise. The correct SQL-spec-compliant behavior of expr = NULL is to always return null (unknown). Therefore this parameter defaults to off.

However, filtered forms in Microsoft Access generate queries that appear to use expr = NULL to test for null values, so if you use that interface to access the database you might want to turn this option on. Since expressions of the form expr = NULL always return the null value (using the SQL standard interpretation), they are not very useful and do not appear often in normal applications so this option does little harm in practice. But new users are frequently confused about the semantics of expressions involving null values, so this option is off by default.

Note that this option only affects the exact form = NULL, not other comparison operators or other expressions that are computationally equivalent to some expression involving the equals operator (such as IN). Thus, this option is not a general fix for bad programming.

Refer to Section 9.2 for related information.

18.14. Memory Purge

Postgres Pro Standard provides memory purge configuration parameters that can automatically replace data with zero bytes before it is deleted. For details, see Section 31.1.

wipe_file_on_delete (boolean)

Replace a file with zero bytes before it is deleted.

Default: on

wipe_heaptuple_on_delete (boolean)

Replace a row version with zero bytes before it is deleted.

Default: on

wipe_memctx_on_free (boolean)

Clear random-access memory before it is freed. This parameter only controls the memory allocated as part of a particular context.
Server Configuration

Default: on
done

Default: on

18.15. Error Handling

exit_on_error (boolean)

If on, any error will terminate the current session. By default, this is set to off, so that only FATAL errors will terminate the session.

restart_after_crash (boolean)

When set to on, which is the default, Postgres Pro will automatically reinitialize after a backend crash. Leaving this value set to on is normally the best way to maximize the availability of the database. However, in some circumstances, such as when Postgres Pro is being invoked by clusterware, it may be useful to disable the restart so that the clusterware can gain control and take any actions it deems appropriate.

This parameter can only be set in the postgresql.conf file or on the server command line.

data_sync_retry (boolean)

When set to off, which is the default, Postgres Pro will raise a PANIC-level error on failure to flush modified data files to the file system. This causes the database server to crash. This parameter can only be set at server start.

On some operating systems, the status of data in the kernel's page cache is unknown after a write-back failure. In some cases it might have been entirely forgotten, making it unsafe to retry; the second attempt may be reported as successful, when in fact the data has been lost. In these circumstances, the only way to avoid data loss is to recover from the WAL after any failure is reported, preferably after investigating the root cause of the failure and replacing any faulty hardware.

If set to on, Postgres Pro will instead report an error but continue to run so that the data flushing operation can be retried in a later checkpoint. Only set it to on after investigating the operating system's treatment of buffered data in case of write-back failure.

recovery_init_sync_method (enum)

When set to fsync, which is the default, PostgreSQL will recursively open and synchronize all files in the data directory before crash recovery begins. The search for files will follow symbolic links for the WAL directory and each configured tablespace (but not any other symbolic links). This is intended to make sure that all WAL and data files are durably stored on disk before replaying changes. This applies whenever starting a database cluster that did not shut down cleanly, including copies created with pg_basebackup.

On Linux, syncfs may be used instead, to ask the operating system to synchronize the whole file systems that contain the data directory, the WAL files and each tablespace (but not any other file systems that may be reachable through symbolic links). This may be a lot faster than the fsync setting, because it doesn't need to open each file one by one. On the other hand, it may be slower if a file system is shared by other applications that modify a lot of files, since those files will also be
written to disk. Furthermore, on versions of Linux before 5.8, I/O errors encountered while writing data to disk may not be reported to PostgreSQL, and relevant error messages may appear only in kernel logs.

This parameter can only be set in the `postgresql.conf` file or on the server command line.

## 18.16. Preset Options

The following “parameters” are read-only. As such, they have been excluded from the sample `postgresql.conf` file. These options report various aspects of Postgres Pro behavior that might be of interest to certain applications, particularly administrative front-ends. Most of them are determined when Postgres Pro is compiled or when it is installed.

**block_size** *(integer)*

Reports the size of a disk block. It is determined by the value of `BLCKSZ` when building the server. The default value is 8192 bytes. The meaning of some configuration variables (such as `shared_buffers`) is influenced by `block_size`. See Section 18.4 for information.

**data_checksums** *(boolean)*

Reports whether data checksums are enabled for this cluster. See data checksums for more information.

**data_directory_mode** *(integer)*

On Unix systems this parameter reports the permissions the data directory (defined by `data_directory`) had at server startup. (On Microsoft Windows this parameter will always display 0700.) See group access for more information.

**debug_assertions** *(boolean)*

Reports whether Postgres Pro has been built with assertions enabled. That is the case if the macro `USE_ASSERT_CHECKING` is defined when Postgres Pro is built (accomplished e.g., by the configure option `--enable-cassert`). By default Postgres Pro is built without assertions.

**integer_datetimes** *(boolean)*

Reports whether Postgres Pro was built with support for 64-bit-integer dates and times. As of Postgres Pro 10, this is always on.

**in_hot_standby** *(boolean)*

Reports whether the server is currently in hot standby mode. When this is on, all transactions are forced to be read-only. Within a session, this can change only if the server is promoted to be primary. See Section 25.4 for more information.

**lc_collate** *(string)*

Reports the locale in which sorting of textual data is done. See Section 22.1 for more information. This value is determined when a database is created.

**lc_collate_canonical** *(string)*

Reports the canonical name of the collation order locale. Unlike `lc_collate`, `lc_collate_canonical` does not contain the modifier of the collation provider.

**lc_ctype** *(string)*

Reports the locale that determines character classifications. See Section 22.1 for more information. This value is determined when a database is created. Ordinarily this will be the same as `lc_collate`, but for special applications it might be set differently.
Server Configuration

max_function_args (integer)
Reports the maximum number of function arguments. It is determined by the value of \texttt{FUNC_MAX_ARGS} when building the server. The default value is 100 arguments.

max_identifier_length (integer)
Reports the maximum identifier length. It is determined as one less than the value of \texttt{NAMEDATALEN} when building the server. The default value of \texttt{NAMEDATALEN} is 64; therefore the default \texttt{max_identifier_length} is 63 bytes, which can be less than 63 characters when using multibyte encodings.

max_index_keys (integer)
Reports the maximum number of index keys. It is determined by the value of \texttt{INDEX_MAX_KEYS} when building the server. The default value is 32 keys.

segment_size (integer)
Reports the number of blocks (pages) that can be stored within a file segment. It is determined by the value of \texttt{RELSEG_SIZE} when building the server. The maximum size of a segment file in bytes is equal to segment_size multiplied by block_size; by default this is 1GB.

server_encoding (string)
Reports the database encoding (character set). It is determined when the database is created. Ordinarily, clients need only be concerned with the value of \texttt{client_encoding}.

server_version (string)
Reports the version number of the server. It is determined by the value of \texttt{PG_VERSION} when building the server.

server_version_num (integer)
Reports the version number of the server as an integer. It is determined by the value of \texttt{PG_VERSION_NUM} when building the server.

ssl_library (string)
Reports the name of the SSL library that this Postgres Pro server was built with (even if SSL is not currently configured or in use on this instance), for example OpenSSL, or an empty string if none.

wal_block_size (integer)
Reports the size of a WAL disk block. It is determined by the value of \texttt{XLOG_BLCKSZ} when building the server. The default value is 8192 bytes.

wal_segment_size (integer)
Reports the size of write ahead log segments. The default value is 16MB. See Section 28.5 for more information.

18.17. Customized Options

This feature was designed to allow parameters not normally known to Postgres Pro to be added by add-on modules (such as procedural languages). This allows extension modules to be configured in the standard ways.

Custom options have two-part names: an extension name, then a dot, then the parameter name proper, much like qualified names in SQL. An example is \texttt{plpgsql.variable_conflict}.

Because custom options may need to be set in processes that have not loaded the relevant extension module, Postgres Pro will accept a setting for any two-part parameter name. Such variables are treated as placeholders and have no function until the module that defines them is loaded. When an extension
module is loaded, it will add its variable definitions, convert any placeholder values according to those definitions, and issue warnings for any unrecognized placeholders that begin with its extension name.

18.18. Developer Options

The following parameters are intended for developer testing, and should never be used on a production database. However, some of them can be used to assist with the recovery of severely damaged databases. As such, they have been excluded from the sample postgresql.conf file. Note that many of these parameters require special source compilation flags to work at all.

allow_system_table_mods (boolean)

Allows modification of the structure of system tables as well as certain other risky actions on system tables. This is otherwise not allowed even for superusers. Ill-advised use of this setting can cause irretrievable data loss or seriously corrupt the database system. Only superusers can change this setting.

backtrace_functions (string)

This parameter contains a comma-separated list of C function names. If an error is raised and the name of the internal C function where the error happens matches a value in the list, then a backtrace is written to the server log together with the error message. This can be used to debug specific areas of the source code.

Backtrace support is not available on all platforms, and the quality of the backtraces depends on compilation options.

This parameter can only be set by superusers.

debug_discard_caches (integer)

When set to 1, each system catalog cache entry is invalidated at the first possible opportunity, whether or not anything that would render it invalid really occurred. Caching of system catalogs is effectively disabled as a result, so the server will run extremely slowly. Higher values run the cache invalidation recursively, which is even slower and only useful for testing the caching logic itself. The default value of 0 selects normal catalog caching behavior.

This parameter can be very helpful when trying to trigger hard-to-reproduce bugs involving concurrent catalog changes, but it is otherwise rarely needed.

This parameter is supported when DISCARD_CACHES_ENABLED was defined at compile time (which happens automatically when using the configure option --enable-cassert). In production builds, its value will always be 0 and attempts to set it to another value will raise an error.

force_parallel_mode (enum)

Allows the use of parallel queries for testing purposes even in cases where no performance benefit is expected. The allowed values of force_parallel_mode are off (use parallel mode only when it is expected to improve performance), on (force parallel query for all queries for which it is thought to be safe), and regress (like on, but with additional behavior changes as explained below).

More specifically, setting this value to on will add a Gather node to the top of any query plan for which this appears to be safe, so that the query runs inside of a parallel worker. Even when a parallel worker is not available or cannot be used, operations such as starting a subtransaction that would be prohibited in a parallel query context will be prohibited unless the planner believes that this will cause the query to fail. If failures or unexpected results occur when this option is set, some functions used by the query may need to be marked PARALLEL UNSAFE (or, possibly, PARALLEL RESTRICTED).

Setting this value to regress has all of the same effects as setting it to on plus some additional effects that are intended to facilitate automated regression testing. Normally, messages from a parallel worker include a context line indicating that, but a setting of regress suppresses this line so that the output is the same as in non-parallel execution. Also, the Gather nodes added to plans by this setting
are hidden in EXPLAIN output so that the output matches what would be obtained if this setting were turned off.

ignore_system_indexes (boolean)

Ignore system indexes when reading system tables (but still update the indexes when modifying the tables). This is useful when recovering from damaged system indexes. This parameter cannot be changed after session start.

post_auth_delay (integer)

The amount of time to delay when a new server process is started, after it conducts the authentication procedure. This is intended to give developers an opportunity to attach to the server process with a debugger. If this value is specified without units, it is taken as seconds. A value of zero (the default) disables the delay. This parameter cannot be changed after session start.

pre_auth_delay (integer)

The amount of time to delay just after a new server process is forked, before it conducts the authentication procedure. This is intended to give developers an opportunity to attach to the server process with a debugger to trace down misbehavior in authentication. If this value is specified without units, it is taken as seconds. A value of zero (the default) disables the delay. This parameter can only be set in the postgresql.conf file or on the server command line.

trace_notify (boolean)

Generates a great amount of debugging output for the LISTEN and NOTIFY commands. client min messages or log_min_messages must be DEBUG1 or lower to send this output to the client or server logs, respectively.

trace_recovery_messages (enum)

Enables logging of recovery-related debugging output that otherwise would not be logged. This parameter allows the user to override the normal setting of log_min_messages, but only for specific messages. This is intended for use in debugging Hot Standby. Valid values are DEBUG5, DEBUG4, DEBUG3, DEBUG2, DEBUG1, and LOG. The default, LOG, does not affect logging decisions at all. The other values cause recovery-related debug messages of that priority or higher to be logged as though they had LOG priority; for common settings of log_min_messages this results in unconditionally sending them to the server log. This parameter can only be set in the postgresql.conf file or on the server command line.

trace_sort (boolean)

If on, emit information about resource usage during sort operations. This parameter is only available if the TRACE_SORT macro was defined when Postgres Pro was compiled. (However, TRACE_SORT is currently defined by default.)

trace_locks (boolean)

If on, emit information about lock usage. Information dumped includes the type of lock operation, the type of lock and the unique identifier of the object being locked or unlocked. Also included are bit masks for the lock types already granted on this object as well as for the lock types awaited on this object. For each lock type a count of the number of granted locks and waiting locks is also dumped as well as the totals. An example of the log file output is shown here:

```
LOG:  LockAcquire: new: lock(0xb7acd844) id(24688,24696,0,0,0,1)
     grantMask(0) req(0,0,0,0,0,0)=0 grant (0,0,0,0,0,0)=0
     wait(0) type(AccessShareLock)
LOG:  GrantLock: lock(0xb7acd844) id(24688,24696,0,0,0,1)
     grantMask(2) req(1,0,0,0,0,0)=1 grant (1,0,0,0,0,0)=1
     wait(0) type(AccessShareLock)
LOG:  UnGrantLock: updated: lock(0xb7acd844) id(24688,24696,0,0,0,1)
     grantMask(0) req(0,0,0,0,0,0)=0 grant (0,0,0,0,0,0)=0
```
Server Configuration

wait(0) type(AccessShareLock)
LOG:  CleanUpLock: deleting: lock(0xb7acd844) id(24688,24696,0,0,0,1)
grantMask(0) req(0,0,0,0,0,0)=0 grant(0,0,0,0,0,0)=0
wait(0) type(INVALID)

This parameter is only available if the LOCK_DEBUG macro was defined when Postgres Pro was compiled.

trace_lwlocks (boolean)
If on, emit information about lightweight lock usage. Lightweight locks are intended primarily to provide mutual exclusion of access to shared-memory data structures.

This parameter is only available if the LOCK_DEBUG macro was defined when Postgres Pro was compiled.

trace_userlocks (boolean)
If on, emit information about user lock usage. Output is the same as for trace_locks, only for advisory locks.

This parameter is only available if the LOCK_DEBUG macro was defined when Postgres Pro was compiled.

trace_lock_oidmin (integer)
If set, do not trace locks for tables below this OID (used to avoid output on system tables).

This parameter is only available if the LOCK_DEBUG macro was defined when Postgres Pro was compiled.

trace_lock_table (integer)
Unconditionally trace locks on this table (OID).

This parameter is only available if the LOCK_DEBUG macro was defined when Postgres Pro was compiled.

debug_deadlocks (boolean)
If set, dumps information about all current locks when a deadlock timeout occurs.

This parameter is only available if the LOCK_DEBUG macro was defined when Postgres Pro was compiled.

log_btree_build_stats (boolean)
If set, logs system resource usage statistics (memory and CPU) on various B-tree operations.

This parameter is only available if the BTREE_BUILD_STATS macro was defined when Postgres Pro was compiled.

wal_consistency_checking (string)
This parameter is intended to be used to check for bugs in the WAL redo routines. When enabled, full-page images of any buffers modified in conjunction with the WAL record are added to the record. If the record is subsequently replayed, the system will first apply each record and then test whether the buffers modified by the record match the stored images. In certain cases (such as hint bits), minor variations are acceptable, and will be ignored. Any unexpected differences will result in a fatal error, terminating recovery.

The default value of this setting is the empty string, which disables the feature. It can be set to all to check all records, or to a comma-separated list of resource managers to check only records originating from those resource managers. Currently, the supported resource managers are heap,
heap2, btree, hash, gin, gist, sequence, spgist, brin, and generic. Only superusers can change this setting.

wal_debug (boolean)

If on, emit WAL-related debugging output. This parameter is only available if the WAL_DEBUG macro was defined when Postgres Pro was compiled.

ignore_checksum_failure (boolean)

Only has effect if data checksums are enabled.

Detection of a checksum failure during a read normally causes Postgres Pro to report an error, aborting the current transaction. Setting ignore_checksum_failure to on causes the system to ignore the failure (but still report a warning), and continue processing. This behavior may cause crashes, propagate or hide corruption, or other serious problems. However, it may allow you to get past the error and retrieve undamaged tuples that might still be present in the table if the block header is still sane. If the header is corrupt an error will be reported even if this option is enabled. The default setting is off, and it can only be changed by a superuser.

zero_damaged_pages (boolean)

Detection of a damaged page header normally causes Postgres Pro to report an error, aborting the current transaction. Setting zero_damaged_pages to on causes the system to instead report a warning, zero out the damaged page in memory, and continue processing. This behavior will destroy data, namely all the rows on the damaged page. However, it does allow you to get past the error and retrieve rows from any undamaged pages that might be present in the table. It is useful for recovering data if corruption has occurred due to a hardware or software error. You should generally not set this on until you have given up hope of recovering data from the damaged pages of a table. Zeroed-out pages are not forced to disk so it is recommended to recreate the table or the index before turning this parameter off again. The default setting is off, and it can only be changed by a superuser.

ignore_invalid_pages (boolean)

If set to off (the default), detection of WAL records having references to invalid pages during recovery causes PostgreSQL to raise a PANIC-level error, aborting the recovery. Setting ignore_invalid_pages to on causes the system to ignore invalid page references in WAL records (but still report a warning), and continue the recovery. This behavior may cause crashes, data loss, propagate or hide corruption, or other serious problems. However, it may allow you to get past the PANIC-level error, to finish the recovery, and to cause the server to start up. The parameter can only be set at server start. It only has effect during recovery or in standby mode.

jit_debugging_support (boolean)

If LLVM has the required functionality, register generated functions with GDB. This makes debugging easier. The default setting is off. This parameter can only be set at server start.

jit_dump_bitcode (boolean)

Writes the generated LLVM IR out to the file system, inside data directory. This is only useful for working on the internals of the JIT implementation. The default setting is off. This parameter can only be changed by a superuser.

jit_expressions (boolean)

Determines whether expressions are JIT compiled, when JIT compilation is activated (see Section 30.2). The default is on.

jit_profiling_support (boolean)

If LLVM has the required functionality, emit the data needed to allow perf to profile functions generated by JIT. This writes out files to ~/.debug/jit/; the user is responsible for performing cleanup when desired. The default setting is off. This parameter can only be set at server start.
Server Configuration

jit_tuple_deforming (boolean)

Determines whether tuple deforming is JIT compiled, when JIT compilation is activated (see Section 30.2). The default is on.

remove_temp_files_after_crash (boolean)

When set to on, which is the default, PostgreSQL will automatically remove temporary files after a backend crash. If disabled, the files will be retained and may be used for debugging, for example. Repeated crashes may however result in accumulation of useless files. This parameter can only be set in the postgresql.conf file or on the server command line.

18.19. Short Options

For convenience there are also single letter command-line option switches available for some parameters. They are described in Table 18.3. Some of these options exist for historical reasons, and their presence as a single-letter option does not necessarily indicate an endorsement to use the option heavily.

Table 18.3. Short Option Key

<table>
<thead>
<tr>
<th>Short Option</th>
<th>Equivalent</th>

</table>
Chapter 19. Client Authentication

When a client application connects to the database server, it specifies which Postgres Pro database user name it wants to connect as, much the same way one logs into a Unix computer as a particular user. Within the SQL environment the active database user name determines access privileges to database objects — see Chapter 20 for more information. Therefore, it is essential to restrict which database users can connect.

Note

As explained in Chapter 20, Postgres Pro actually does privilege management in terms of “roles”. In this chapter, we consistently use database user to mean “role with the LOGIN privilege”.

Authentication is the process by which the database server establishes the identity of the client, and by extension determines whether the client application (or the user who runs the client application) is permitted to connect with the database user name that was requested.

Postgres Pro offers a number of different client authentication methods. The method used to authenticate a particular client connection can be selected on the basis of (client) host address, database, and user.

Postgres Pro database user names are logically separate from user names of the operating system in which the server runs. If all the users of a particular server also have accounts on the server’s machine, it makes sense to assign database user names that match their operating system user names. However, a server that accepts remote connections might have many database users who have no local operating system account, and in such cases there need be no connection between database user names and OS user names.

19.1. The pg_hba.conf File

Client authentication is controlled by a configuration file, which traditionally is named pg_hba.conf and is stored in the database cluster's data directory. (HBA stands for host-based authentication.) A default pg_hba.conf file is installed when the data directory is initialized by initdb. It is possible to place the authentication configuration file elsewhere, however; see the hba_file configuration parameter.

The general format of the pg_hba.conf file is a set of records, one per line. Blank lines are ignored, as is any text after the # comment character. A record can be continued onto the next line by ending the line with a backslash. (Backslashes are not special except at the end of a line.) A record is made up of a number of fields which are separated by spaces and/or tabs. Fields can contain white space if the field value is double-quoted. Quoting one of the keywords in a database, user, or address field (e.g., all or replication) makes the word lose its special meaning, and just match a database, user, or host with that name. Backslash line continuation applies even within quoted text or comments.

Each record specifies a connection type, a client IP address range (if relevant for the connection type), a database name, a user name, and the authentication method to be used for connections matching these parameters. The first record with a matching connection type, client address, requested database, and user name is used to perform authentication. There is no “fall-through” or “backup”: if one record is chosen and the authentication fails, subsequent records are not considered. If no record matches, access is denied.

A record can have several formats:

- local
- host
- hostssl
- hostnossl
- hostgssenc
- hostnogssenc
- host
- hostssl

561
The meaning of the fields is as follows:

**local**

This record matches connection attempts using Unix-domain sockets. Without a record of this type, Unix-domain socket connections are disallowed.

**host**

This record matches connection attempts made using TCP/IP. **host** records match SSL or non-SSL connection attempts as well as GSSAPI encrypted or non-GSSAPI encrypted connection attempts.

**Note**

Remote TCP/IP connections will not be possible unless the server is started with an appropriate value for the `listen_addresses` configuration parameter, since the default behavior is to listen for TCP/IP connections only on the local loopback address `localhost`.

**hostssl**

This record matches connection attempts made using TCP/IP, but only when the connection is made with SSL encryption.

To make use of this option the server must be built with SSL support. Furthermore, SSL must be enabled by setting the `ssl` configuration parameter (see Section 17.9 for more information). Otherwise, the **hostssl** record is ignored except for logging a warning that it cannot match any connections.

**hostnossl**

This record type has the opposite behavior of **hostssl**; it only matches connection attempts made over TCP/IP that do not use SSL.

**hostgssenc**

This record matches connection attempts made using TCP/IP, but only when the connection is made with GSSAPI encryption.

To make use of this option the server must be built with GSSAPI support. Otherwise, the **hostgssenc** record is ignored except for logging a warning that it cannot match any connections.

**hostnogssenc**

This record type has the opposite behavior of **hostgssenc**; it only matches connection attempts made over TCP/IP that do not use GSSAPI encryption.

**database**

Specifies which database name(s) this record matches. The value `all` specifies that it matches all databases. The value `sameuser` specifies that the record matches if the requested database has the same name as the requested user. The value `samerole` specifies that the requested user must be a member of the role with the same name as the requested database. (`samegroup` is an obsolete but still accepted spelling of `samerole`.) Superusers are not considered to be members of a role for the purposes of `samerole` unless they are explicitly members of the role, directly or indirectly, and not just by virtue of being a superuser. The value `replication` specifies that the record matches if a physical replication connection is requested, however, it doesn’t match with logical replication connections. Note that physical replication connections do not specify any particular database whereas logical replication connections do specify it. Otherwise, this is the name of a specific Postgres Pro database. Multiple database names can be supplied by separating them with commas. A separate file containing database names can be specified by preceding the file name with `@`.

Client Authentication

user

Specifies which database user name(s) this record matches. The value all specifies that it matches all users. Otherwise, this is either the name of a specific database user, or a group name preceded by +. (Recall that there is no real distinction between users and groups in Postgres Pro; a + mark really means “match any of the roles that are directly or indirectly members of this role”, while a name without a + mark matches only that specific role.) For this purpose, a superuser is only considered to be a member of a role if they are explicitly a member of the role, directly or indirectly, and not just by virtue of being a superuser. Multiple user names can be supplied by separating them with commas. A separate file containing user names can be specified by preceding the file name with @.

address

Specifies the client machine address(es) that this record matches. This field can contain either a host name, an IP address range, or one of the special key words mentioned below.

An IP address range is specified using standard numeric notation for the range's starting address, then a slash (/) and a CIDR mask length. The mask length indicates the number of high-order bits of the client IP address that must match. Bits to the right of this should be zero in the given IP address. There must not be any white space between the IP address, the /, and the CIDR mask length.

Typical examples of an IPv4 address range specified this way are 172.20.143.89/32 for a single host, or 172.20.143.0/24 for a small network, or 10.6.0.0/16 for a larger one. An IPv6 address range might look like ::1/128 for a single host (in this case the IPv6 loopback address) or fe80::7a31:c1ff:0000:0000/96 for a small network. 0.0.0.0/0 represents all IPv4 addresses, and ::/0 represents all IPv6 addresses. To specify a single host, use a mask length of 32 for IPv4 or 128 for IPv6. In a network address, do not omit trailing zeroes.

An entry given in IPv4 format will match only IPv4 connections, and an entry given in IPv6 format will match only IPv6 connections, even if the represented address is in the IPv4-in-IPv6 range. Note that entries in IPv6 format will be rejected if the system's C library does not have support for IPv6 addresses.

You can also write all to match any IP address, samehost to match any of the server's own IP addresses, or samenet to match any address in any subnet that the server is directly connected to.

If a host name is specified (anything that is not an IP address range or a special key word is treated as a host name), that name is compared with the result of a reverse name resolution of the client's IP address (e.g., reverse DNS lookup, if DNS is used). Host name comparisons are case insensitive. If there is a match, then a forward name resolution (e.g., forward DNS lookup) is performed on the host name to check whether any of the addresses it resolves to are equal to the client's IP address. If both directions match, then the entry is considered to match. (The host name that is used in pg_hba.conf should be the one that address-to-name resolution of the client's IP address returns, otherwise the line won't be matched. Some host name databases allow associating an IP address with multiple host names, but the operating system will only return one host name when asked to resolve an IP address.)

A host name specification that starts with a dot (.) matches a suffix of the actual host name. So .example.com would match foo.example.com (but not just example.com).

When host names are specified in pg_hba.conf, you should make sure that name resolution is reasonably fast. It can be of advantage to set up a local name resolution cache such as nscd. Also, you may wish to enable the configuration parameter log_hostname to see the client's host name instead of the IP address in the log.

These fields do not apply to local records.

Note

Users sometimes wonder why host names are handled in this seemingly complicated way, with two name resolutions including a reverse lookup of the client’s IP address. This complicates
use of the feature in case the client's reverse DNS entry is not set up or yields some undesirable host name. It is done primarily for efficiency: this way, a connection attempt requires at most two resolver lookups, one reverse and one forward. If there is a resolver problem with some address, it becomes only that client's problem. A hypothetical alternative implementation that only did forward lookups would have to resolve every host name mentioned in \texttt{pg\_hba.conf} during every connection attempt. That could be quite slow if many names are listed. And if there is a resolver problem with one of the host names, it becomes everyone's problem.

Also, a reverse lookup is necessary to implement the suffix matching feature, because the actual client host name needs to be known in order to match it against the pattern.

Note that this behavior is consistent with other popular implementations of host name-based access control, such as the Apache HTTP Server and TCP Wrappers.

\textbf{IP-address}
\textbf{IP-mask}

These two fields can be used as an alternative to the \textit{IP-address/mask-length} notation. Instead of specifying the mask length, the actual mask is specified in a separate column. For example, 255.0.0.0 represents an IPv4 CIDR mask length of 8, and 255.255.255.255 represents a CIDR mask length of 32.

These fields do not apply to local records.

\textbf{auth-method}

Specifies the authentication method to use when a connection matches this record. The possible choices are summarized here; details are in Section 19.3.

\textbf{trust}

Allow the connection unconditionally. This method allows anyone that can connect to the Postgres Pro database server to login as any Postgres Pro user they wish, without the need for a password or any other authentication. See Section 19.4 for details.

\textbf{reject}

Reject the connection unconditionally. This is useful for “filtering out” certain hosts from a group, for example a \texttt{reject} line could block a specific host from connecting, while a later line allows the remaining hosts in a specific network to connect.

\textbf{scram-sha-256}

Perform SCRAM-SHA-256 authentication to verify the user's password. See Section 19.5 for details.

\textbf{md5}

Perform SCRAM-SHA-256 or MD5 authentication to verify the user's password. See Section 19.5 for details.

\textbf{password}

Require the client to supply an unencrypted password for authentication. Since the password is sent in clear text over the network, this should not be used on untrusted networks. See Section 19.5 for details.

\textbf{gss}

Use GSSAPI to authenticate the user. This is only available for TCP/IP connections. See Section 19.6 for details. It can be used in conjunction with GSSAPI encryption.

\textbf{sspi}

Use SSPI to authenticate the user. This is only available on Windows. See Section 19.7 for details.
Client Authentication

ident
Obtain the operating system user name of the client by contacting the ident server on the client and check if it matches the requested database user name. Ident authentication can only be used on TCP/IP connections. When specified for local connections, peer authentication will be used instead. See Section 19.8 for details.

peer
Obtain the client’s operating system user name from the operating system and check if it matches the requested database user name. This is only available for local connections. See Section 19.9 for details.

ldap
Authenticate using an LDAP server. See Section 19.10 for details.

radius
Authenticate using a RADIUS server. See Section 19.11 for details.

cert
Authenticate using SSL client certificates. See Section 19.12 for details.

pam
Authenticate using the Pluggable Authentication Modules (PAM) service provided by the operating system. See Section 19.13 for details.

bsd
Authenticate using the BSD Authentication service provided by the operating system. See Section 19.14 for details.

auth-options
After the auth-method field, there can be field(s) of the form name=value that specify options for the authentication method. Details about which options are available for which authentication methods appear below.

In addition to the method-specific options listed below, there is a method-independent authentication option clientcert, which can be specified in any hostssl record. This option can be set to verify-ca or verify-full. Both options require the client to present a valid (trusted) SSL certificate, while verify-full additionally enforces that the cn (Common Name) in the certificate matches the username or an applicable mapping. This behavior is similar to the cert authentication method (see Section 19.12) but enables pairing the verification of client certificates with any authentication method that supports hostssl entries.

On any record using client certificate authentication (i.e. one using the cert authentication method or one using the clientcert option), you can specify which part of the client certificate credentials to match using the clientname option. This option can have one of two values. If you specify clientname=CN, which is the default, the username is matched against the certificate’s Common Name (CN). If instead you specify clientname=DN the username is matched against the entire Distinguished Name (DN) of the certificate. This option is probably best used in conjunction with a username map. The comparison is done with the DN in RFC 2253 format. To see the DN of a client certificate in this format, do

openssl x509 -in myclient.crt -noout --subject -nameopt RFC2253 | sed "s/ ^subject=//"

Care needs to be taken when using this option, especially when using regular expression matching against the DN.

Files included by @ constructs are read as lists of names, which can be separated by either whitespace or commas. Comments are introduced by #, just as in pg_hba.conf, and nested @ constructs are allowed.
Unless the file name following @ is an absolute path, it is taken to be relative to the directory containing the referencing file.

Since the pg_hba.conf records are examined sequentially for each connection attempt, the order of the records is significant. Typically, earlier records will have tight connection match parameters and weaker authentication methods, while later records will have looser match parameters and stronger authentication methods. For example, one might wish to use trust authentication for local TCP/IP connections but require a password for remote TCP/IP connections. In this case a record specifying trust authentication for connections from 127.0.0.1 would appear before a record specifying password authentication for a wider range of allowed client IP addresses.

The pg_hba.conf file is read on start-up and when the main server process receives a SIGHUP signal. If you edit the file on an active system, you will need to signal the postmaster (using pg_ctl reload, calling the SQL function pg_reload_conf(), or using kill -HUP) to make it re-read the file.

**Note**

The preceding statement is not true on Microsoft Windows: there, any changes in the pg_hba.conf file are immediately applied by subsequent new connections.

The system view pg_hba_file_rules can be helpful for pre-testing changes to the pg_hba.conf file, or for diagnosing problems if loading of the file did not have the desired effects. Rows in the view with non-null error fields indicate problems in the corresponding lines of the file.

**Tip**

To connect to a particular database, a user must not only pass the pg_hba.conf checks, but must have the CONNECT privilege for the database. If you wish to restrict which users can connect to which databases, it's usually easier to control this by granting/revoking CONNECT privilege than to put the rules in pg_hba.conf entries.

Some examples of pg_hba.conf entries are shown in Example 19.1. See the next section for details on the different authentication methods.

**Example 19.1. Example pg_hba.conf Entries**

```
# Allow any user on the local system to connect to any database with
# any database user name using Unix-domain sockets (the default for local
# connections).
#
# TYPE  DATABASE    USER    ADDRESS          METHOD
local  all         all     all              trust

# The same using local loopback TCP/IP connections.
#
# TYPE  DATABASE    USER    ADDRESS          METHOD
host   all         all     127.0.0.1/32     trust

# The same as the previous line, but using a separate netmask column
#
# TYPE  DATABASE    USER    IP-ADDRESS      IP-MASK            METHOD
host   all         all     127.0.0.1      255.255.255.255     trust

# The same over IPv6.
#
# TYPE  DATABASE    USER    ADDRESS          METHOD
host   all         all     ::1/128          trust
```
# The same using a host name (would typically cover both IPv4 and IPv6).
#

</table>

# The last two lines above can be combined into a single line:

| local | all             | @admins,+support |                     | md5    |

# The database column can also use lists and file names:

| local | db1,db2,@demodbs | all             |                     | md5    |

### 19.2. User Name Maps

When using an external authentication system such as Ident or GSSAPI, the name of the operating system user that initiated the connection might not be the same as the database user (role) that is to be used. In this case, a user name map can be applied to map the operating system user name to a database user. To use user name mapping, specify `map=map-name` in the options field in `pg_hba.conf`. This option is supported for all authentication methods that receive external user names. Since different mappings might be needed for different connections, the name of the map to be used is specified in the `map-name` parameter in `pg_hba.conf` to indicate which map to use for each individual connection.

User name maps are defined in the ident map file, which by default is named `pg_ident.conf` and is stored in the cluster’s data directory. (It is possible to place the map file elsewhere, however; see the `ident_file` configuration parameter.) The ident map file contains lines of the general form:

```
map-name  system-username  database-username
```

Comments, whitespace and line continuations are handled in the same way as in `pg_hba.conf`. The `map-name` is an arbitrary name that will be used to refer to this mapping in `pg_hba.conf`. The other two fields specify an operating system user name and a matching database user name. The same `map-name` can be used repeatedly to specify multiple user-mappings within a single map.

There is no restriction regarding how many database users a given operating system user can correspond to, nor vice versa. Thus, entries in a map should be thought of as meaning “this operating system user is allowed to connect as this database user”, rather than implying that they are equivalent. The connection will be allowed if there is any map entry that pairs the user name obtained from the external authentication system with the database user name that the user has requested to connect as.

If the `system-username` field starts with a slash (/), the remainder of the field is treated as a regular expression. (See Section 9.7.3.1 for details of Postgres Pro’s regular expression syntax.) The regular expression can include a single capture, or parenthesized subexpression, which can then be referenced in the `database-username` field as `\1` (backslash-one). This allows the mapping of multiple user names in a single line, which is particularly useful for simple syntax substitutions. For example, these entries

```
mymap  /^\.(.*)@mydomain\.com$/  \1
mymap  /^\.(.*)@otherdomain\.com$/  guest
```

will remove the domain part for users with system user names that end with `@mydomain.com`, and allow any user whose system name ends with `@otherdomain.com` to log in as `guest`.

#### Tip

Keep in mind that by default, a regular expression can match just part of a string. It’s usually wise to use `^` and `$`, as shown in the above example, to force the match to be to the entire system user name.

The `pg_ident.conf` file is read on start-up and when the main server process receives a SIGHUP signal. If you edit the file on an active system, you will need to signal the postmaster (using `pg_ctl reload`, calling the SQL function `pg_reload_conf()`, or using `kill -HUP`) to make it re-read the file.
Client Authentication

A `pg_ident.conf` file that could be used in conjunction with the `pg_hba.conf` file in Example 19.1 is shown in Example 19.2. In this example, anyone logged in to a machine on the 192.168 network that does not have the operating system user name `bryanh`, `ann`, or `robert` would not be granted access. Unix user `robert` would only be allowed access when he tries to connect as Postgres Pro user `bob`, not as `robert` or anyone else. `ann` would only be allowed to connect as `ann`. User `bryanh` would be allowed to connect as either `bryanh` or as `guest1`.

Example 19.2. An Example `pg_ident.conf` File

```
# MAPNAME       SYSTEM-USERNAME         PG-USERNAME
omicron         bryanh                  bryanh
omicron         ann                     ann
# bob has user name robert on these machines
omicron         robert                  bob
# bryanh can also connect as guest1
omicron         bryanh                  guest1
```

19.3. Authentication Methods

Postgres Pro provides various methods for authenticating users:

- **Trust authentication**, which simply trusts that users are who they say they are.
- **Password authentication**, which requires that users send a password.
- **GSSAPI authentication**, which relies on a GSSAPI-compatible security library. Typically this is used to access an authentication server such as a Kerberos or Microsoft Active Directory server.
- **SSPI authentication**, which uses a Windows-specific protocol similar to GSSAPI.
- **Ident authentication**, which relies on an “Identification Protocol” (RFC 1413) service on the client's machine. (On local Unix-socket connections, this is treated as peer authentication.)
- **Peer authentication**, which relies on operating system facilities to identify the process at the other end of a local connection. This is not supported for remote connections.
- **LDAP authentication**, which relies on an LDAP authentication server.
- **RADIUS authentication**, which relies on a RADIUS authentication server.
- **Certificate authentication**, which requires an SSL connection and authenticates users by checking the SSL certificate they send.
- **PAM authentication**, which relies on a PAM (Pluggable Authentication Modules) library.
- **BSD authentication**, which relies on the BSD Authentication framework (currently available only on OpenBSD).

Peer authentication is usually recommendable for local connections, though trust authentication might be sufficient in some circumstances. Password authentication is the easiest choice for remote connections. All the other options require some kind of external security infrastructure (usually an authentication server or a certificate authority for issuing SSL certificates), or are platform-specific.

The following sections describe each of these authentication methods in more detail.

19.4. Trust Authentication

When `trust` authentication is specified, Postgres Pro assumes that anyone who can connect to the server is authorized to access the database with whatever database user name they specify (even superuser names). Of course, restrictions made in the `database` and `user` columns still apply. This method should only be used when there is adequate operating-system-level protection on connections to the server.

`trust` authentication is appropriate and very convenient for local connections on a single-user workstation. It is usually *not* appropriate by itself on a multiuser machine. However, you might be able to use `trust` even on a multiuser machine, if you restrict access to the server's Unix-domain
Client Authentication

socket file using file-system permissions. To do this, set the `unix_socket_permissions` (and possibly `unix_socket_group`) configuration parameters as described in Section 18.3. Or you could set the `unix_socket_directories` configuration parameter to place the socket file in a suitably restricted directory.

Setting file-system permissions only helps for Unix-socket connections. Local TCP/IP connections are not restricted by file-system permissions. Therefore, if you want to use file-system permissions for local security, remove the host ... 127.0.0.1 ... line from `pg_hba.conf`, or change it to a non-trust authentication method.

trust authentication is only suitable for TCP/IP connections if you trust every user on every machine that is allowed to connect to the server by the `pg_hba.conf` lines that specify trust. It is seldom reasonable to use trust for any TCP/IP connections other than those from localhost (127.0.0.1).

19.5. Password Authentication

There are several password-based authentication methods. These methods operate similarly but differ in how the users' passwords are stored on the server and how the password provided by a client is sent across the connection.

scram-sha-256

The method `scram-sha-256` performs SCRAM-SHA-256 authentication, as described in RFC 7677. It is a challenge-response scheme that prevents password sniffing on untrusted connections and supports storing passwords on the server in a cryptographically hashed form that is thought to be secure.

This is the most secure of the currently provided methods, but it is not supported by older client libraries.

md5

The method `md5` uses a custom less secure challenge-response mechanism. It prevents password sniffing and avoids storing passwords on the server in plain text but provides no protection if an attacker manages to steal the password hash from the server. Also, the MD5 hash algorithm is nowadays no longer considered secure against determined attacks.

The `md5` method cannot be used with the `db_user_namespace` feature.

To ease transition from the `md5` method to the newer SCRAM method, if `md5` is specified as a method in `pg_hba.conf` but the user's password on the server is encrypted for SCRAM (see below), then SCRAM-based authentication will automatically be chosen instead.

password

The method `password` sends the password in clear-text and is therefore vulnerable to password “sniffing” attacks. It should always be avoided if possible. If the connection is protected by SSL encryption then `password` can be used safely, though. (Though SSL certificate authentication might be a better choice if one is depending on using SSL).

Postgres Pro database passwords are separate from operating system user passwords. The password for each database user is stored in the `pg_authid` system catalog. Passwords can be managed with the SQL commands `CREATE ROLE` and `ALTER ROLE`, e.g., `CREATE ROLE foo WITH LOGIN PASSWORD 'secret'`, or the `psql` command `\password`. If no password has been set up for a user, the stored password is null and password authentication will always fail for that user.

The availability of the different password-based authentication methods depends on how a user's password on the server is encrypted (or hashed, more accurately). This is controlled by the configuration parameter `password_encryption` at the time the password is set. If a password was encrypted using the `scram-sha-256` setting, then it can be used for the authentication methods `scram-sha-256` and `password` (but password transmission will be in plain text in the latter case). The authentication method
specification md5 will automatically switch to using the scram-sha-256 method in this case, as explained above, so it will also work. If a password was encrypted using the md5 setting, then it can be used only for the md5 and password authentication method specifications (again, with the password transmitted in plain text in the latter case). (Previous Postgres Pro releases supported storing the password on the server in plain text. This is no longer possible.) To check the currently stored password hashes, see the system catalog pg_authid.

To upgrade an existing installation from md5 to scram-sha-256, after having ensured that all client libraries in use are new enough to support SCRAM, set password_encryption = 'scram-sha-256' in postgresql.conf, make all users set new passwords, and change the authentication method specifications in pg_hba.conf to scram-sha-256.

19.6. GSSAPI Authentication

GSSAPI is an industry-standard protocol for secure authentication defined in RFC 2743. Postgres Pro supports GSSAPI for authentication, communications encryption, or both. GSSAPI provides automatic authentication (single sign-on) for systems that support it. The authentication itself is secure. If GSSAPI encryption or SSL encryption is used, the data sent along the database connection will be encrypted; otherwise, it will not.

GSSAPI support has to be enabled when Postgres Pro Standard is built.

When GSSAPI uses Kerberos, it uses a standard service principal (authentication identity) name in the format servicename/hostname@realm. The principal name used by a particular installation is not encoded in the Postgres Pro server in any way; rather it is specified in the keytab file that the server reads to determine its identity. If multiple principals are listed in the keytab file, the server will accept any one of them. The server's realm name is the preferred realm specified in the Kerberos configuration file(s) accessible to the server.

When connecting, the client must know the principal name of the server it intends to connect to. The servicename part of the principal is ordinarily postgres, but another value can be selected via libpq's krbsrvname connection parameter. The hostname part is the fully qualified host name that libpq is told to connect to. The realm name is the preferred realm specified in the Kerberos configuration file(s) accessible to the client.

The client will also have a principal name for its own identity (and it must have a valid ticket for this principal). To use GSSAPI for authentication, the client principal must be associated with a Postgres Pro database user name. The pg_ident.conf configuration file can be used to map principals to user names; for example, pgusername@realm could be mapped to just pgusername. Alternatively, you can use the full username@realm principal as the role name in Postgres Pro without any mapping.

Postgres Pro also supports mapping client principals to user names by just stripping the realm from the principal. This method is supported for backwards compatibility and is strongly discouraged as it is then impossible to distinguish different users with the same user name but coming from different realms. To enable this, set include_realm to 0. For simple single-realm installations, doing that combined with setting the krb_realm parameter (which checks that the principal's realm matches exactly what is in the krb_realm parameter) is still secure; but this is a less capable approach compared to specifying an explicit mapping in pg_ident.conf.

The location of the server's keytab file is specified by the krb_server_keyfile configuration parameter. For security reasons, it is recommended to use a separate keytab just for the Postgres Pro server rather than allowing the server to read the system keytab file. Make sure that your server keytab file is readable (and preferably only readable, not writable) by the Postgres Pro server account. (See also Section 17.1.)

The keytab file is generated using the Kerberos software; see the Kerberos documentation for details. The following example shows doing this using the kadmin tool of MIT-compatible Kerberos 5 implementations:

```sh
ekadmin% addprinc -randkey postgres/server.my.domain.org
kekadmin% ktadd -k krb5.keytab postgres/server.my.domain.org
```
Client Authentication

The following authentication options are supported for the GSSAPI authentication method:

**include_realm**

If set to 0, the realm name from the authenticated user principal is stripped off before being passed through the user name mapping (Section 19.2). This is discouraged and is primarily available for backwards compatibility, as it is not secure in multi-realm environments unless *krb_realm* is also used. It is recommended to leave *include_realm* set to the default (1) and to provide an explicit mapping in *pg_ident.conf* to convert principal names to Postgres Pro user names.

**map**

Allows mapping from client principals to database user names. See Section 19.2 for details. For a GSSAPI/Kerberos principal, such as `username@EXAMPLE.COM` (or, less commonly, `username/hostbased@EXAMPLE.COM`), the user name used for mapping is `username@EXAMPLE.COM` (or `username/hostbased@EXAMPLE.COM`, respectively), unless *include_realm* has been set to 0, in which case `username` (or `username/hostbased`) is what is seen as the system user name when mapping.

**krb_realm**

Sets the realm to match user principal names against. If this parameter is set, only users of that realm will be accepted. If it is not set, users of any realm can connect, subject to whatever user name mapping is done.

In addition to these settings, which can be different for different *pg_hba.conf* entries, there is the server-wide *krb_caseins_users* configuration parameter. If that is set to true, client principals are matched to user map entries case-insensitively. *krb_realm*, if set, is also matched case-insensitively.

### 19.7. SSPI Authentication

SSPI is a Windows technology for secure authentication with single sign-on. Postgres Pro will use SSPI in **negotiate** mode, which will use Kerberos when possible and automatically fall back to NTLM in other cases. SSPI authentication only works when both server and client are running Windows, or, on non-Windows platforms, when GSSAPI is available.

When using Kerberos authentication, SSPI works the same way GSSAPI does; see Section 19.6 for details.

The following configuration options are supported for SSPI:

**include_realm**

If set to 0, the realm name from the authenticated user principal is stripped off before being passed through the user name mapping (Section 19.2). This is discouraged and is primarily available for backwards compatibility, as it is not secure in multi-realm environments unless *krb_realm* is also used. It is recommended to leave *include_realm* set to the default (1) and to provide an explicit mapping in *pg_ident.conf* to convert principal names to Postgres Pro user names.

**compat_realm**

If set to 1, the domain's SAM-compatible name (also known as the NetBIOS name) is used for the *include_realm* option. This is the default. If set to 0, the true realm name from the Kerberos user principal name is used.

Do not disable this option unless your server runs under a domain account (this includes virtual service accounts on a domain member system) and all clients authenticating through SSPI are also using domain accounts, or authentication will fail.

**upn_username**

If this option is enabled along with *compat_realm*, the user name from the Kerberos UPN is used for authentication. If it is disabled (the default), the SAM-compatible user name is used. By default, these two names are identical for new user accounts.
Note that libpq uses the SAM-compatible name if no explicit user name is specified. If you use libpq or a driver based on it, you should leave this option disabled or explicitly specify user name in the connection string.

map

Allows for mapping between system and database user names. See Section 19.2 for details. For an SSPI/Kerberos principal, such as username@EXAMPLE.COM (or, less commonly, username/hostbased@EXAMPLE.COM), the user name used for mapping is username@EXAMPLE.COM (or username/hostbased@EXAMPLE.COM, respectively), unless include_realm has been set to 0, in which case username (or username/hostbased) is what is seen as the system user name when mapping.

krb_realm

Sets the realm to match user principal names against. If this parameter is set, only users of that realm will be accepted. If it is not set, users of any realm can connect, subject to whatever user name mapping is done.

19.8. Ident Authentication

The ident authentication method works by obtaining the client's operating system user name from an ident server and using it as the allowed database user name (with an optional user name mapping). This is only supported on TCP/IP connections.

Note

When ident is specified for a local (non-TCP/IP) connection, peer authentication (see Section 19.9) will be used instead.

The following configuration options are supported for ident:

map

Allows for mapping between system and database user names. See Section 19.2 for details.

The "Identification Protocol" is described in RFC 1413. Virtually every Unix-like operating system ships with an ident server that listens on TCP port 113 by default. The basic functionality of an ident server is to answer questions like “What user initiated the connection that goes out of your port $X$ and connects to my port $Y$?”. Since Postgres Pro knows both $X$ and $Y$ when a physical connection is established, it can interrogate the ident server on the host of the connecting client and can theoretically determine the operating system user for any given connection.

The drawback of this procedure is that it depends on the integrity of the client: if the client machine is untrusted or compromised, an attacker could run just about any program on port 113 and return any user name they choose. This authentication method is therefore only appropriate for closed networks where each client machine is under tight control and where the database and system administrators operate in close contact. In other words, you must trust the machine running the ident server. Heed the warning:

The Identification Protocol is not intended as an authorization or access control protocol.

—RFC 1413

Some ident servers have a nonstandard option that causes the returned user name to be encrypted, using a key that only the originating machine’s administrator knows. This option must not be used when using the ident server with Postgres Pro, since Postgres Pro does not have any way to decrypt the returned string to determine the actual user name.

19.9. Peer Authentication
Client Authentication

The peer authentication method works by obtaining the client's operating system user name from the
kernel and using it as the allowed database user name (with optional user name mapping). This method
is only supported on local connections.

The following configuration options are supported for peer:

map

Allows for mapping between system and database user names. See Section 19.2 for details.

Peer authentication is only available on operating systems providing the getpeereid() function, the
SO_PEERCRED socket parameter, or similar mechanisms. Currently that includes Linux, most flavors of
BSD including macOS, and Solaris.

19.10. LDAP Authentication

This authentication method operates similarly to password except that it uses LDAP as the password
verification method. LDAP is used only to validate the user name/password pairs. Therefore the user
must already exist in the database before LDAP can be used for authentication.

LDAP authentication can operate in two modes. In the first mode, which we will call the simple bind
mode, the server will bind to the distinguished name constructed as prefix username suffix. Typically,
the prefix parameter is used to specify cn=, or DOMAIN\ in an Active Directory environment. suffix is
used to specify the remaining part of the DN in a non-Active Directory environment.

In the second mode, which we will call the search+bind mode, the server first binds to the LDAP directory
with a fixed user name and password, specified with ldapbinddn and ldapbindpasswd, and performs a
search for the user trying to log in to the database. If no user and password is configured, an anonymous
bind will be attempted to the directory. The search will be performed over the subtree at ldapbasedn,
and will try to do an exact match of the attribute specified in ldapsearchattribute. Once the user has
been found in this search, the server disconnects and re-binds to the directory as this user, using the
password specified by the client, to verify that the login is correct. This mode is the same as that used by
LDAP authentication schemes in other software, such as Apache mod_authnz_ldap and pam_ldap. This
method allows for significantly more flexibility in where the user objects are located in the directory, but
will cause two separate connections to the LDAP server to be made.

The following configuration options are used in both modes:

ldapserver

Names or IP addresses of LDAP servers to connect to. Multiple servers may be specified, separated
by spaces.

ldapport

Port number on LDAP server to connect to. If no port is specified, the LDAP library's default port
setting will be used.

ldapscheme

Set to ldaps to use LDAPS. This is a non-standard way of using LDAP over SSL, supported by some
LDAP server implementations. See also the ldaptls option for an alternative.

ldapstarttls

Set to 1 to make the connection between Postgres Pro and the LDAP server use TLS encryption. This
uses the StartTLS operation per RFC 4513. See also the ldapscheme option for an alternative.

Note that using ldapscheme or ldapstarttls only encrypts the traffic between the Postgres Pro server and
the LDAP server. The connection between the Postgres Pro server and the Postgres Pro client will still
be unencrypted unless SSL is used there as well.

The following options are used in simple bind mode only:
Client Authentication

**ldapprefix**
String to prepend to the user name when forming the DN to bind as, when doing simple bind authentication.

**ldapsuffix**
String to append to the user name when forming the DN to bind as, when doing simple bind authentication.

The following options are used in search+bind mode only:

**ldapbasedn**
Root DN to begin the search for the user in, when doing search+bind authentication.

**ldapbinddn**
DN of user to bind to the directory with to perform the search when doing search+bind authentication.

**ldapbindpasswd**
Password for user to bind to the directory with to perform the search when doing search+bind authentication.

**ldapsearchattribute**
Attribute to match against the user name in the search when doing search+bind authentication. If no attribute is specified, the uid attribute will be used.

**ldapsearchfilter**
The search filter to use when doing search+bind authentication. Occurrences of $username will be replaced with the user name. This allows for more flexible search filters than ldapsearchattribute.

**ldapurl**
An RFC 4516 LDAP URL. This is an alternative way to write some of the other LDAP options in a more compact and standard form. The format is

```
ldap[s]://host[:port]/basedn[?[attribute][?[scope][?[filter]]]]
```

- `scope` must be one of `base`, `one`, `sub`, typically the last. (The default is `base`, which is normally not useful in this application.) `attribute` can nominate a single attribute, in which case it is used as a value for `ldapsearchattribute`. If `attribute` is empty then `filter` can be used as a value for `ldapsearchfilter`.

The URL scheme ldaps chooses the LDAPS method for making LDAP connections over SSL, equivalent to using `ldapscheme=ldaps`. To use encrypted LDAP connections using the StartTLS operation, use the normal URL scheme `ldap` and specify the `ldaptls` option in addition to `ldapurl`.

For non-anonymous binds, `ldapbinddn` and `ldapbindpasswd` must be specified as separate options.

LDAP URLs are currently only supported with OpenLDAP, not on Windows.

It is an error to mix configuration options for simple bind with options for search+bind.

When using search+bind mode, the search can be performed using a single attribute specified with `ldapsearchattribute`, or using a custom search filter specified with `ldapsearchfilter`. Specifying `ldapsearchattribute=foo` is equivalent to specifying `ldapsearchfilter=\"(foo=$username)\"`. If neither option is specified the default is `ldapsearchattribute=uid`.

If Postgres Pro was compiled with OpenLDAP as the LDAP client library, the `ldapspecifier` setting may be omitted. In that case, a list of host names and ports is looked up via RFC 2782 DNS SRV records. The name `_ldap._tcp.DOMAIN` is looked up, where `DOMAIN` is extracted from `ldapbasedn`.

575
Here is an example for a simple-bind LDAP configuration:

```plaintext
host ... ldap ldapserver=ldap.example.net ldapprefix="cn=" ldapsuffix=", dc=example, dc=net"
```

When a connection to the database server as database user `someuser` is requested, Postgres Pro will attempt to bind to the LDAP server using the DN `cn=someuser, dc=example, dc=net` and the password provided by the client. If that connection succeeds, the database access is granted.

Here is an example for a search+bind configuration:

```plaintext
host ... ldap ldapserver=ldap.example.net ldapbasedn="dc=example, dc=net"
ldapsearchattribute=uid
```

When a connection to the database server as database user `someuser` is requested, Postgres Pro will attempt to bind anonymously (since `ldapbinddn` was not specified) to the LDAP server, perform a search for `(uid=someuser)` under the specified base DN. If an entry is found, it will then attempt to bind using that found information and the password supplied by the client. If that second connection succeeds, the database access is granted.

Here is the same search+bind configuration written as a URL:

```plaintext
host ... ldap ldapurl="ldap://ldap.example.net/dc=example,dc=net?uid?sub"
```

Some other software that supports authentication against LDAP uses the same URL format, so it will be easier to share the configuration.

Here is an example for a search+bind configuration that uses `ldapsearchfilter` instead of `ldapsearchattribute` to allow authentication by user ID or email address:

```plaintext
host ... ldap ldapserver=ldap.example.net ldapbasedn="dc=example, dc=net"
ldapsearchfilter="(|(uid=$username)(mail=$username))"
```

Here is an example for a search+bind configuration that uses DNS SRV discovery to find the host name(s) and port(s) for the LDAP service for the domain name `example.net`:

```plaintext
host ... ldap ldapbasedn="dc=example,dc=net"
```

**Tip**

Since LDAP often uses commas and spaces to separate the different parts of a DN, it is often necessary to use double-quoted parameter values when configuring LDAP options, as shown in the examples.

### 19.11. RADIUS Authentication

This authentication method operates similarly to password except that it uses RADIUS as the password verification method. RADIUS is used only to validate the user name/password pairs. Therefore the user must already exist in the database before RADIUS can be used for authentication.

When using RADIUS authentication, an Access Request message will be sent to the configured RADIUS server. This request will be of type Authenticate Only, and include parameters for `user name`, `password` (encrypted) and `NAS Identifier`. The request will be encrypted using a secret shared with the server. The RADIUS server will respond to this request with either `Access Accept` or `Access Reject`. There is no support for RADIUS accounting.

Multiple RADIUS servers can be specified, in which case they will be tried sequentially. If a negative response is received from a server, the authentication will fail. If no response is received, the next server in the list will be tried. To specify multiple servers, separate the server names with commas and surround the list with double quotes. If multiple servers are specified, the other RADIUS options can also be given as comma-separated lists, to provide individual values for each server. They can also be specified as a single value, in which case that value will apply to all servers.
The following configuration options are supported for RADIUS:

**radiusservers**

The DNS names or IP addresses of the RADIUS servers to connect to. This parameter is required.

**radiussecrets**

The shared secrets used when talking securely to the RADIUS servers. This must have exactly the same value on the Postgres Pro and RADIUS servers. It is recommended that this be a string of at least 16 characters. This parameter is required.

**Note**

The encryption vector used will only be cryptographically strong if Postgres Pro is built with support for OpenSSL. In other cases, the transmission to the RADIUS server should only be considered obfuscated, not secured, and external security measures should be applied if necessary.

**radiusports**

The port numbers to connect to on the RADIUS servers. If no port is specified, the default RADIUS port (1812) will be used.

**radiusidentifiers**

The strings to be used as NAS Identifier in the RADIUS requests. This parameter can be used, for example, to identify which database cluster the user is attempting to connect to, which can be useful for policy matching on the RADIUS server. If no identifier is specified, the default `postgresql` will be used.

If it is necessary to have a comma or whitespace in a RADIUS parameter value, that can be done by putting double quotes around the value, but it is tedious because two layers of double-quoting are now required. An example of putting whitespace into RADIUS secret strings is:

```
host ... radius radiusservers="server1,server2" radiussecrets=""secret one",""secret two"
```

### 19.12. Certificate Authentication

This authentication method uses SSL client certificates to perform authentication. It is therefore only available for SSL connections. When using this authentication method, the server will require that the client provide a valid, trusted certificate. No password prompt will be sent to the client. The `cn` (Common Name) attribute of the certificate will be compared to the requested database user name, and if they match the login will be allowed. User name mapping can be used to allow `cn` to be different from the database user name.

The following configuration options are supported for SSL certificate authentication:

**map**

Allows for mapping between system and database user names. See Section 19.2 for details.

It is redundant to use the `clientcert` option with `cert` authentication because `cert` authentication is effectively `trust` authentication with `clientcert=verify-full`.

### 19.13. PAM Authentication

This authentication method operates similarly to `password` except that it uses PAM (Pluggable Authentication Modules) as the authentication mechanism. The default PAM service name is `postgresql`. PAM is used only to validate user name/password pairs and optionally the connected remote host name.
or IP address. Therefore the user must already exist in the database before PAM can be used for authentication. For more information about PAM, please read the Linux-PAM Page.

The following configuration options are supported for PAM:

```
pamservice
  PAM service name.
```

```
pam_use_hostname
  Determines whether the remote IP address or the host name is provided to PAM modules through the PAM_RHOST item. By default, the IP address is used. Set this option to 1 to use the resolved host name instead. Host name resolution can lead to login delays. (Most PAM configurations don't use this information, so it is only necessary to consider this setting if a PAM configuration was specifically created to make use of it.)
```

**Note**

If PAM is set up to read /etc/shadow, authentication will fail because the Postgres Pro server is started by a non-root user. However, this is not an issue when PAM is configured to use LDAP or other authentication methods.

### 19.14. BSD Authentication

This authentication method operates similarly to password except that it uses BSD Authentication to verify the password. BSD Authentication is used only to validate user name/password pairs. Therefore the user's role must already exist in the database before BSD Authentication can be used for authentication. The BSD Authentication framework is currently only available on OpenBSD.

BSD Authentication in Postgres Pro uses the auth-postgresql login type and authenticates with the postgresql login class if that's defined in login.conf. By default that login class does not exist, and Postgres Pro will use the default login class.

**Note**

To use BSD Authentication, the Postgres Pro user account (that is, the operating system user running the server) must first be added to the auth group. The auth group exists by default on OpenBSD systems.

### 19.15. Authentication Problems

Authentication failures and related problems generally manifest themselves through error messages like the following:

```
FATAL:  no pg_hba.conf entry for host "123.123.123.123", user "andym", database "testdb"
```

This is what you are most likely to get if you succeed in contacting the server, but it does not want to talk to you. As the message suggests, the server refused the connection request because it found no matching entry in its pg_hba.conf configuration file.

```
FATAL:  password authentication failed for user "andym"
```

Messages like this indicate that you contacted the server, and it is willing to talk to you, but not until you pass the authorization method specified in the pg_hba.conf file. Check the password you are providing, or check your Kerberos or ident software if the complaint mentions one of those authentication types.
FATAL: user "andym" does not exist
The indicated database user name was not found.

FATAL: database "testdb" does not exist
The database you are trying to connect to does not exist. Note that if you do not specify a database name, it defaults to the database user name, which might or might not be the right thing.

Tip
The server log might contain more information about an authentication failure than is reported to the client. If you are confused about the reason for a failure, check the server log.
Chapter 20. Database Roles

Postgres Pro manages database access permissions using the concept of roles. A role can be thought of as either a database user, or a group of database users, depending on how the role is set up. Roles can own database objects (for example, tables and functions) and can assign privileges on those objects to other roles to control who has access to which objects. Furthermore, it is possible to grant membership in a role to another role, thus allowing the member role to use privileges assigned to another role.

The concept of roles subsumes the concepts of “users” and “groups”. In PostgreSQL versions before 8.1, users and groups were distinct kinds of entities, but now there are only roles. Any role can act as a user, a group, or both.

This chapter describes how to create and manage roles. More information about the effects of role privileges on various database objects can be found in Section 5.7.

20.1. Database Roles

Database roles are conceptually completely separate from operating system users. In practice it might be convenient to maintain a correspondence, but this is not required. Database roles are global across a database cluster installation (and not per individual database). To create a role use the CREATE ROLE SQL command:

CREATE ROLE name;

name follows the rules for SQL identifiers: either unadorned without special characters, or double-quoted. (In practice, you will usually want to add additional options, such as LOGIN, to the command. More details appear below.) To remove an existing role, use the analogous DROP ROLE command:

DROP ROLE name;

For convenience, the programs createuser and dropuser are provided as wrappers around these SQL commands that can be called from the shell command line:

createuser name
dropuser name

To determine the set of existing roles, examine the pg_roles system catalog, for example

SELECT rolname FROM pg_roles;

The psql program's \du meta-command is also useful for listing the existing roles.

In order to bootstrap the database system, a freshly initialized system always contains one predefined role. This role is always a “superuser”, and by default (unless altered when running initdb) it will have the same name as the operating system user that initialized the database cluster. Customarily, this role will be named postgres. In order to create more roles you first have to connect as this initial role.

Every connection to the database server is made using the name of some particular role, and this role determines the initial access privileges for commands issued in that connection. The role name to use for a particular database connection is indicated by the client that is initiating the connection request in an application-specific fashion. For example, the psql program uses the -U command line option to indicate the role to connect as. Many applications assume the name of the current operating system user by default (including createuser and psql). Therefore it is often convenient to maintain a naming correspondence between roles and operating system users.

The set of database roles a given client connection can connect as is determined by the client authentication setup, as explained in Chapter 19. (Thus, a client is not limited to connect as the role matching its operating system user, just as a person’s login name need not match his or her real name.) Since the role identity determines the set of privileges available to a connected client, it is important to carefully configure privileges when setting up a multiuser environment.
20.2. Role Attributes

A database role can have a number of attributes that define its privileges and interact with the client authentication system.

**login privilege**

Only roles that have the `LOGIN` attribute can be used as the initial role name for a database connection. A role with the `LOGIN` attribute can be considered the same as a “database user”. To create a role with login privilege, use either:

```
CREATE ROLE name LOGIN;
CREATE USER name;
```

*CREATE USER is equivalent to CREATE ROLE except that CREATE USER includes LOGIN by default, while CREATE ROLE does not.*

**superuser status**

A database superuser bypasses all permission checks, except the right to log in. This is a dangerous privilege and should not be used carelessly; it is best to do most of your work as a role that is not a superuser. To create a new database superuser, use `CREATE ROLE name SUPERUSER`. You must do this as a role that is already a superuser.

**database creation**

A role must be explicitly given permission to create databases (except for superusers, since those bypass all permission checks). To create such a role, use `CREATE ROLE name CREATEDB`.

**role creation**

A role must be explicitly given permission to create more roles (except for superusers, since those bypass all permission checks). To create such a role, use `CREATE ROLE name CREATEROLE`. A role with `CREATEROLE` privilege can alter and drop other roles, too, as well as grant or revoke membership in them. However, to create, alter, drop, or change membership of a superuser role, superuser status is required; `CREATEROLE` is insufficient for that.

**initiating replication**

A role must explicitly be given permission to initiate streaming replication (except for superusers, since those bypass all permission checks). A role used for streaming replication must have `LOGIN` permission as well. To create such a role, use `CREATE ROLE name REPLICATION LOGIN`.

**password**

A password is only significant if the client authentication method requires the user to supply a password when connecting to the database. The `password` and `md5` authentication methods make use of passwords. Database passwords are separate from operating system passwords. Specify a password upon role creation with `CREATE ROLE name PASSWORD 'string'`.

A role’s attributes can be modified after creation with `ALTER ROLE`. See the reference pages for the `CREATE ROLE` and `ALTER ROLE` commands for details.

**Tip**

It is good practice to create a role that has the `CREATEDB` and `CREATEROLE` privileges, but is not a superuser, and then use this role for all routine management of databases and roles. This approach avoids the dangers of operating as a superuser for tasks that do not really require it.

A role can also have role-specific defaults for many of the run-time configuration settings described in Chapter 18. For example, if for some reason you want to disable index scans (hint: not a good idea) anytime you connect, you can use:

```
ALTER ROLE myname SET enable_indexscan TO off;
```
This will save the setting (but not set it immediately). In subsequent connections by this role it will appear as though \texttt{SET enable_indexscan TO off} had been executed just before the session started. You can still alter this setting during the session; it will only be the default. To remove a role-specific default setting, use \texttt{ALTER ROLE rolename RESET varname}. Note that role-specific defaults attached to roles without \texttt{LOGIN} privilege are fairly useless, since they will never be invoked.

20.3. Role Membership

It is frequently convenient to group users together to ease management of privileges: that way, privileges can be granted to, or revoked from, a group as a whole. In Postgres Pro this is done by creating a role that represents the group, and then granting \texttt{membership} in the group role to individual user roles.

To set up a group role, first create the role:

\begin{verbatim}
CREATE ROLE name;
\end{verbatim}

Typically a role being used as a group would not have the \texttt{LOGIN} attribute, though you can set it if you wish.

Once the group role exists, you can add and remove members using the \texttt{GRANT} and \texttt{REVOKE} commands:

\begin{verbatim}
GRANT group_role TO role1, ...;
REVOKE group_role FROM role1, ...;
\end{verbatim}

You can grant membership to other group roles, too (since there isn't really any distinction between group roles and non-group roles). The database will not let you set up circular membership loops. Also, it is not permitted to grant membership in a role to \texttt{PUBLIC}.

The members of a group role can use the privileges of the role in two ways. First, every member of a group can explicitly do \texttt{SET ROLE} to temporarily “become” the group role. In this state, the database session has access to the privileges of the group role rather than the original login role, and any database objects created are considered owned by the group role not the login role. Second, member roles that have the \texttt{INHERIT} attribute automatically have use of the privileges of roles of which they are members, including any privileges inherited by those roles. As an example, suppose we have done:

\begin{verbatim}
CREATE ROLE joe LOGIN INHERIT;
CREATE ROLE admin NOINHERIT;
CREATE ROLE wheel NOINHERIT;
GRANT admin TO joe;
GRANT wheel TO admin;
\end{verbatim}

Immediately after connecting as role \texttt{joe}, a database session will have use of privileges granted directly to \texttt{joe} plus any privileges granted to \texttt{admin}, because \texttt{joe} “inherits” \texttt{admin's} privileges. However, privileges granted to \texttt{wheel} are not available, because even though \texttt{joe} is indirectly a member of \texttt{wheel}, the membership is via \texttt{admin} which has the \texttt{NOINHERIT} attribute. After:

\begin{verbatim}
SET ROLE admin;
\end{verbatim}

the session would have use of only those privileges granted to \texttt{admin}, and not those granted to \texttt{joe}. After:

\begin{verbatim}
SET ROLE wheel;
\end{verbatim}

the session would have use of only those privileges granted to \texttt{wheel}, and not those granted to either \texttt{joe} or \texttt{admin}. The original privilege state can be restored with any of:

\begin{verbatim}
SET ROLE joe;
SET ROLE NONE;
RESET ROLE;
\end{verbatim}

Note

The \texttt{SET ROLE} command always allows selecting any role that the original login role is directly or indirectly a member of. Thus, in the above example, it is not necessary to become \texttt{admin} before becoming \texttt{wheel}.
Note

In the SQL standard, there is a clear distinction between users and roles, and users do not automatically inherit privileges while roles do. This behavior can be obtained in Postgres Pro by giving roles being used as SQL roles the `INHERIT` attribute, while giving roles being used as SQL users the `NOINHERIT` attribute. However, Postgres Pro defaults to giving all roles the `INHERIT` attribute, for backward compatibility with pre-8.1 releases in which users always had use of permissions granted to groups they were members of.

The role attributes `LOGIN`, `SUPERUSER`, `CREATEDB`, and `CREATEROLE` can be thought of as special privileges, but they are never inherited as ordinary privileges on database objects are. You must actually `SET ROLE` to a specific role having one of these attributes in order to make use of the attribute. Continuing the above example, we might choose to grant `CREATEDB` and `CREATEROLE` to the `admin` role. Then a session connecting as role `joe` would not have these privileges immediately, only after doing `SET ROLE admin`.

To destroy a group role, use `DROP ROLE`:

```
DROP ROLE name;
```

Any memberships in the group role are automatically revoked (but the member roles are not otherwise affected).

## 20.4. Dropping Roles

Because roles can own database objects and can hold privileges to access other objects, dropping a role is often not just a matter of a quick `DROP ROLE`. Any objects owned by the role must first be dropped or reassigned to other owners; and any permissions granted to the role must be revoked.

Ownership of objects can be transferred one at a time using `ALTER` commands, for example:

```
ALTER TABLE bobs_table OWNER TO alice;
```

Alternatively, the `REASSIGN OWNED` command can be used to reassign ownership of all objects owned by the role-to-be-dropped to a single other role. Because `REASSIGN OWNED` cannot access objects in other databases, it is necessary to run it in each database that contains objects owned by the role. (Note that the first such `REASSIGN OWNED` will change the ownership of any shared-across-databases objects, that is databases or tablespaces, that are owned by the role-to-be-dropped.)

Once any valuable objects have been transferred to new owners, any remaining objects owned by the role-to-be-dropped can be dropped with the `DROP OWNED` command. Again, this command cannot access objects in other databases, so it is necessary to run it in each database that contains objects owned by the role. Also, `DROP OWNED` will not drop entire databases or tablespaces, so it is necessary to do that manually if the role owns any databases or tablespaces that have not been transferred to new owners.

`DROP OWNED` also takes care of removing any privileges granted to the target role for objects that do not belong to it. Because `REASSIGN OWNED` does not touch such objects, it’s typically necessary to run both `REASSIGN OWNED` and `DROP OWNED` (in that order!) to fully remove the dependencies of a role to be dropped.

In short then, the most general recipe for removing a role that has been used to own objects is:

```
REASSIGN OWNED BY doomed_role TO successor_role;
DROP OWNED BY doomed_role;
-- repeat the above commands in each database of the cluster
DROP ROLE doomed_role;
```

When not all owned objects are to be transferred to the same successor owner, it’s best to handle the exceptions manually and then perform the above steps to mop up.

If `DROP ROLE` is attempted while dependent objects still remain, it will issue messages identifying which objects need to be reassigned or dropped.
20.5. Predefined Roles

Postgres Pro provides a set of predefined roles that provide access to certain, commonly needed, privileged capabilities and information. Administrators (including roles that have the CREATEROLE privilege) can GRANT these roles to users and/or other roles in their environment, providing those users with access to the specified capabilities and information.

The predefined roles are described in Table 20.1. Note that the specific permissions for each of the roles may change in the future as additional capabilities are added. Administrators should monitor the release notes for changes.

### Table 20.1. Predefined Roles

<table>
<thead>
<tr>
<th>Role</th>
<th>Allowed Access</th>
</tr>
</thead>
<tbody>
<tr>
<td>pg_read_all_data</td>
<td>Read all data (tables, views, sequences), as if having SELECT rights on those objects, and USAGE rights on all schemas, even without having it explicitly. This role does not have the role attribute BYPASSRLS set. If RLS is being used, an administrator may wish to set BYPASSRLS on roles which this role is GRANTed to.</td>
</tr>
<tr>
<td>pg_write_all_data</td>
<td>Write all data (tables, views, sequences), as if having INSERT, UPDATE, and DELETE rights on those objects, and USAGE rights on all schemas, even without having it explicitly. This role does not have the role attribute BYPASSRLS set. If RLS is being used, an administrator may wish to set BYPASSRLS on roles which this role is GRANTed to.</td>
</tr>
<tr>
<td>pg_read_all_settings</td>
<td>Read all configuration variables, even those normally visible only to superusers.</td>
</tr>
<tr>
<td>pg_read_all_stats</td>
<td>Read all pg_stat_* views and use various statistics related extensions, even those normally visible only to superusers.</td>
</tr>
<tr>
<td>pg_stat_scan_tables</td>
<td>Execute monitoring functions that may take ACCESS SHARE locks on tables, potentially for a long time.</td>
</tr>
<tr>
<td>pg_monitor</td>
<td>Read/execute various monitoring views and functions. This role is a member of pg_read_all_settings, pg_read_all_stats and pg_stat_scan_tables.</td>
</tr>
<tr>
<td>pg_database_owner</td>
<td>None. Membership consists, implicitly, of the current database owner.</td>
</tr>
<tr>
<td>pg_signal_backend</td>
<td>Signal another backend to cancel a query or terminate its session.</td>
</tr>
<tr>
<td>pg_read_server_files</td>
<td>Allow reading files from any location the database can access on the server with COPY and other file-access functions.</td>
</tr>
<tr>
<td>pg_write_server_files</td>
<td>Allow writing to files in any location the database can access on the server with COPY and other file-access functions.</td>
</tr>
<tr>
<td>pg_execute_server_program</td>
<td>Allow executing programs on the database server as the user the database runs as with COPY and other functions which allow executing a server-side program.</td>
</tr>
</tbody>
</table>

The pg_monitor, pg_read_all_settings, pg_read_all_stats and pg_stat_scan_tables roles are intended to allow administrators to easily configure a role for the purpose of monitoring the database server. They grant a set of common privileges allowing the role to read various useful configuration settings, statistics and other system information normally restricted to superusers.

The pg_database_owner role has one implicit, situation-dependent member, namely the owner of the current database. The role conveys no rights at first. Like any role, it can own objects or receive grants of access privileges. Consequently, once pg_database_owner has rights within a template database, each owner of a database instantiated from that template will exercise those rights. pg_database_owner cannot be a member of any role, and it cannot have non-implicit members.
Database Roles

The `pg_signal_backend` role is intended to allow administrators to enable trusted, but non-superuser, roles to send signals to other backends. Currently this role enables sending of signals for canceling a query on another backend or terminating its session. A user granted this role cannot however send signals to a backend owned by a superuser. See Section 9.27.2.

The `pg_read_server_files`, `pg_write_server_files` and `pg_execute_server_program` roles are intended to allow administrators to have trusted, but non-superuser, roles which are able to access files and run programs on the database server as the user the database runs as. As these roles are able to access any file on the server file system, they bypass all database-level permission checks when accessing files directly and they could be used to gain superuser-level access, therefore great care should be taken when granting these roles to users.

Care should be taken when granting these roles to ensure they are only used where needed and with the understanding that these roles grant access to privileged information.

Administrators can grant access to these roles to users using the `GRANT` command, for example:

```
GRANT pg_signal_backend TO admin_user;
```

### 20.6. Function Security

Functions, triggers and row-level security policies allow users to insert code into the backend server that other users might execute unintentionally. Hence, these mechanisms permit users to “Trojan horse” others with relative ease. The strongest protection is tight control over who can define objects. Where that is infeasible, write queries referring only to objects having trusted owners. Remove from `search_path` the public schema and any other schemas that permit untrusted users to create objects.

Functions run inside the backend server process with the operating system permissions of the database server daemon. If the programming language used for the function allows unchecked memory accesses, it is possible to change the server's internal data structures. Hence, among many other things, such functions can circumvent any system access controls. Function languages that allow such access are considered “untrusted”, and Postgres Pro allows only superusers to create functions written in those languages.
Chapter 21. Managing Databases

Every instance of a running Postgres Pro server manages one or more databases. Databases are therefore the topmost hierarchical level for organizing SQL objects (“database objects”). This chapter describes the properties of databases, and how to create, manage, and destroy them.

21.1. Overview

A small number of objects, like role, database, and tablespace names, are defined at the cluster level and stored in the pg_global tablespace. Inside the cluster are multiple databases, which are isolated from each other but can access cluster-level objects. Inside each database are multiple schemas, which contain objects like tables and functions. So the full hierarchy is: cluster, database, schema, table (or some other kind of object, such as a function).

When connecting to the database server, a client must specify the database name in its connection request. It is not possible to access more than one database per connection. However, clients can open multiple connections to the same database, or different databases. Database-level security has two components: access control (see Section 19.1), managed at the connection level, and authorization control (see Section 5.7), managed via the grant system. Foreign data wrappers (see postgres_fdw) allow for objects within one database to act as proxies for objects in other database or clusters. The older dblink module (see dblink) provides a similar capability. By default, all users can connect to all databases using all connection methods.

If one Postgres Pro server cluster is planned to contain unrelated projects or users that should be, for the most part, unaware of each other; it is recommended to put them into separate databases and adjust authorizations and access controls accordingly. If the projects or users are interrelated, and thus should be able to use each other's resources, they should be put in the same database but probably into separate schemas; this provides a modular structure with namespace isolation and authorization control. More information about managing schemas is in Section 5.9.

While multiple databases can be created within a single cluster, it is advised to consider carefully whether the benefits outweigh the risks and limitations. In particular, the impact that having a shared WAL (see Chapter 28) has on backup and recovery options. While individual databases in the cluster are isolated when considered from the user's perspective, they are closely bound from the database administrator's point-of-view.

Databases are created with the CREATE DATABASE command (see Section 21.2) and destroyed with the DROP DATABASE command (see Section 21.5). To determine the set of existing databases, examine the pg_database system catalog, for example

SELECT datname FROM pg_database;

The psql program's \l meta-command and -l command-line option are also useful for listing the existing databases.

Note

The SQL standard calls databases “catalogs”, but there is no difference in practice.

21.2. Creating a Database

In order to create a database, the Postgres Pro server must be up and running (see Section 17.3).

Databases are created with the SQL command CREATE DATABASE:

CREATE DATABASE name;

where name follows the usual rules for SQL identifiers. The current role automatically becomes the owner of the new database. It is the privilege of the owner of a database to remove it later (which also removes all the objects in it, even if they have a different owner).
Managing Databases

The creation of databases is a restricted operation. See Section 20.2 for how to grant permission.

Since you need to be connected to the database server in order to execute the `CREATE DATABASE` command, the question remains how the first database at any given site can be created. The first database is always created by the `initdb` command when the data storage area is initialized. (See Section 17.2.) This database is called `postgres`. So to create the first “ordinary” database you can connect to `postgres`.

A second database, `template1`, is also created during database cluster initialization. Whenever a new database is created within the cluster, `template1` is essentially cloned. This means that any changes you make in `template1` are propagated to all subsequently created databases. Because of this, avoid creating objects in `template1` unless you want them propagated to every newly created database. More details appear in Section 21.3.

As a convenience, there is a program you can execute from the shell to create new databases, `createdb`.

```
createdb dbname
```

`createdb` does no magic. It connects to the `postgres` database and issues the `CREATE DATABASE` command, exactly as described above. The `createdb` reference page contains the invocation details. Note that `createdb` without any arguments will create a database with the current user name.

```
Chapter 19 contains information about how to restrict who can connect to a given database.
```

Sometimes you want to create a database for someone else, and have them become the owner of the new database, so they can configure and manage it themselves. To achieve that, use one of the following commands:

```
CREATE DATABASE dbname OWNER rolename;
```

from the SQL environment, or:

```
createdb -O rolename dbname
```

from the shell. Only the superuser is allowed to create a database for someone else (that is, for a role you are not a member of).

**21.3. Template Databases**

`CREATE DATABASE` actually works by copying an existing database. By default, it copies the standard system database named `template1`. Thus that database is the “template” from which new databases are made. If you add objects to `template1`, these objects will be copied into subsequently created user databases. This behavior allows site-local modifications to the standard set of objects in databases. For example, if you install the procedural language PL/Perl in `template1`, it will automatically be available in user databases without any extra action being taken when those databases are created.

There is a second standard system database named `template0`. This database contains the same data as the initial contents of `template1`, that is, only the standard objects predefined by your version of Postgres Pro. `template0` should never be changed after the database cluster has been initialized. By instructing `CREATE DATABASE` to copy `template0` instead of `template1`, you can create a “pristine” user database (one where no user-defined objects exist and where the system objects have not been altered) that contains none of the site-local additions in `template1`. This is particularly handy when restoring a `pg_dump` dump: the dump script should be restored in a pristine database to ensure that one recreates the correct contents of the dumped database, without conflicting with objects that might have been added to `template1` later on.

Another common reason for copying `template0` instead of `template1` is that new encoding and locale settings can be specified when copying `template0`, whereas a copy of `template1` must use the same
settings it does. This is because template1 might contain encoding-specific or locale-specific data, while template0 is known not to.

To create a database by copying template0, use:

```
CREATE DATABASE dbname TEMPLATE template0;
```

from the SQL environment, or:

```
createdb -T template0 dbname
```

from the shell.

It is possible to create additional template databases, and indeed one can copy any database in a cluster by specifying its name as the template for `CREATE DATABASE`. It is important to understand, however, that this is not (yet) intended as a general-purpose “COPY DATABASE” facility. The principal limitation is that no other sessions can be connected to the source database while it is being copied. `CREATE DATABASE` will fail if any other connection exists when it starts; during the copy operation, new connections to the source database are prevented.

Two useful flags exist in `pg_database` for each database: the columns `datistemplate` and `datallowconn`. `datistemplate` can be set to indicate that a database is intended as a template for `CREATE DATABASE`. If this flag is set, the database can be cloned by any user with `CREATEDB` privileges; if it is not set, only superusers and the owner of the database can clone it. If `datallowconn` is false, then no new connections to that database will be allowed (but existing sessions are not terminated simply by setting the flag false). The `template0` database is normally marked `datallowconn = false` to prevent its modification. Both `template0` and `template1` should always be marked with `datistemplate = true`.

```
template1 and template0 do not have any special status beyond the fact that the name template1 is the default source database name for `CREATE DATABASE`. For example, one could drop template1 and recreate it from template0 without any ill effects. This course of action might be advisable if one has carelessly added a bunch of junk in template1. (To delete template1, it must have `pg_database.datistemplate = false`.)

The postgres database is also created when a database cluster is initialized. This database is meant as a default database for users and applications to connect to. It is simply a copy of template1 and can be dropped and recreated if necessary.
```

**Note**

```
21.4. Database Configuration

Recall from Chapter 18 that the Postgres Pro server provides a large number of run-time configuration variables. You can set database-specific default values for many of these settings.

For example, if for some reason you want to disable the GEQO optimizer for a given database, you'd ordinarily have to either disable it for all databases or make sure that every connecting client is careful to issue `SET geqo TO off`. To make this setting the default within a particular database, you can execute the command:

```
ALTER DATABASE mydb SET geqo TO off;
```

This will save the setting (but not set it immediately). In subsequent connections to this database it will appear as though `SET geqo TO off` had been executed just before the session started. Note that users can still alter this setting during their sessions; it will only be the default. To undo any such setting, use `ALTER DATABASE dbname RESET varname`.

21.5. Destroying a Database

Databases are destroyed with the command `DROP DATABASE`:
DROP DATABASE name;

Only the owner of the database, or a superuser, can drop a database. Dropping a database removes all objects that were contained within the database. The destruction of a database cannot be undone.

You cannot execute the `DROP DATABASE` command while connected to the victim database. You can, however, be connected to any other database, including the `template1` database. `template1` would be the only option for dropping the last user database of a given cluster.

For convenience, there is also a shell program to drop databases, `dropdb`:

`dropdb dbname`

(Unlike `createdb`, it is not the default action to drop the database with the current user name.)

## 21.6. Tablespaces

Tablespaces in Postgres Pro allow database administrators to define locations in the file system where the files representing database objects can be stored. Once created, a tablespace can be referred to by name when creating database objects.

By using tablespaces, an administrator can control the disk layout of a Postgres Pro installation. This is useful in at least two ways. First, if the partition or volume on which the cluster was initialized runs out of space and cannot be extended, a tablespace can be created on a different partition and used until the system can be reconfigured.

Second, tablespaces allow an administrator to use knowledge of the usage pattern of database objects to optimize performance. For example, an index which is very heavily used can be placed on a very fast, highly available disk, such as an expensive solid state device. At the same time a table storing archived data which is rarely used or not performance critical could be stored on a less expensive, slower disk system.

### Warning

Even though located outside the main Postgres Pro data directory, tablespaces are an integral part of the database cluster and cannot be treated as an autonomous collection of data files. They are dependent on metadata contained in the main data directory, and therefore cannot be attached to a different database cluster or backed up individually. Similarly, if you lose a tablespace (file deletion, disk failure, etc), the database cluster might become unreadable or unable to start. Placing a tablespace on a temporary file system like a RAM disk risks the reliability of the entire cluster.

To define a tablespace, use the `CREATE TABLESPACE` command, for example::

`CREATE TABLESPACE fastspace LOCATION '/ssd1/postgresql/data';`

The location must be an existing, empty directory that is owned by the Postgres Pro operating system user. All objects subsequently created within the tablespace will be stored in files underneath this directory. The location must not be on removable or transient storage, as the cluster might fail to function if the tablespace is missing or lost.

### Note

There is usually not much point in making more than one tablespace per logical file system, since you cannot control the location of individual files within a logical file system. However, Postgres Pro does not enforce any such limitation, and indeed it is not directly aware of the file system boundaries on your system. It just stores files in the directories you tell it to use.

Creation of the tablespace itself must be done as a database superuser, but after that you can allow ordinary database users to use it. To do that, grant them the `CREATE` privilege on it.
Tables, indexes, and entire databases can be assigned to particular tablespaces. To do so, a user with the `CREATE` privilege on a given tablespace must pass the tablespace name as a parameter to the relevant command. For example, the following creates a table in the tablespace `space1`:

```
CREATE TABLE foo(i int) TABLESPACE space1;
```

Alternatively, use the `default_tablespace` parameter:

```
SET default_tablespace = space1;
CREATE TABLE foo(i int);
```

When `default_tablespace` is set to anything but an empty string, it supplies an implicit `TABLESPACE` clause for `CREATE TABLE` and `CREATE INDEX` commands that do not have an explicit one.

There is also a `temp_tablespaces` parameter, which determines the placement of temporary tables and indexes, as well as temporary files that are used for purposes such as sorting large data sets. This can be a list of tablespace names, rather than only one, so that the load associated with temporary objects can be spread over multiple tablespaces. A random member of the list is picked each time a temporary object is to be created.

The tablespace associated with a database is used to store the system catalogs of that database. Furthermore, it is the default tablespace used for tables, indexes, and temporary files created within the database, if no `TABLESPACE` clause is given and no other selection is specified by `default_tablespace` or `temp_tablespaces` (as appropriate). If a database is created without specifying a tablespace for it, it uses the same tablespace as the template database it is copied from.

Two tablespaces are automatically created when the database cluster is initialized. The `pg_global` tablespace is used for shared system catalogs. The `pg_default` tablespace is the default tablespace of the `template1` and `template0` databases (and, therefore, will be the default tablespace for other databases as well, unless overridden by a `TABLESPACE` clause in `CREATE DATABASE`).

Once created, a tablespace can be used from any database, provided the requesting user has sufficient privilege. This means that a tablespace cannot be dropped until all objects in all databases using the tablespace have been removed.

To remove an empty tablespace, use the `DROP TABLESPACE` command.

To determine the set of existing tablespaces, examine the `pg_tablespace` system catalog, for example:

```
SELECT spcname FROM pg_tablespace;
```

The `psql` program's `\db` meta-command is also useful for listing the existing tablespaces.

Postgres Pro makes use of symbolic links to simplify the implementation of tablespaces. This means that tablespaces can be used only on systems that support symbolic links.

The directory `$PGDATA/pg_tblspc` contains symbolic links that point to each of the non-built-in tablespaces defined in the cluster. Although not recommended, it is possible to adjust the tablespace layout by hand by redefining these links. Under no circumstances perform this operation while the server is running. Note that in PostgreSQL 9.1 and earlier you will also need to update the `pg_tablespace` catalog with the new locations. (If you do not, `pg_dump` will continue to output the old tablespace locations.)
Chapter 22. Localization

This chapter describes the available localization features from the point of view of the administrator. Postgres Pro supports two localization facilities:

- Using the locale features of the operating system to provide locale-specific collation order, number formatting, translated messages, and other aspects. This is covered in Section 22.1 and Section 22.2.
- Providing a number of different character sets to support storing text in all kinds of languages, and providing character set translation between client and server. This is covered in Section 22.3.

22.1. Locale Support

Locale support refers to an application respecting cultural preferences regarding alphabets, sorting, number formatting, etc. Postgres Pro uses the standard ISO C and POSIX locale facilities provided by the server operating system. For additional information refer to the documentation of your system.

22.1.1. Overview

Locale support is automatically initialized when a database cluster is created using initdb. initdb will initialize the database cluster with the locale setting of its execution environment by default, so if your system is already set to use the locale that you want in your database cluster then there is nothing else you need to do. If you want to use a different locale (or you are not sure which locale your system is set to), you can instruct initdb exactly which locale to use by specifying the --locale option. For example:

```
initdb --locale=ru_RU
```

This example for Unix systems sets the locale to Russian (ru) as spoken in Russia (RU). Other possibilities might include en_US (U.S. English) and fr_CA (French Canadian). If more than one character set can be used for a locale then the specifications can take the form language_territory.codeset. For example, fr_BE.UTF-8 represents the French language (fr) as spoken in Belgium (BE), with a UTF-8 character set encoding.

What locales are available on your system under what names depends on what was provided by the operating system vendor and what was installed. On most Unix systems, the command `locale -a` will provide a list of available locales. Windows uses more verbose locale names, such as German_Germany or Swedish_Sweden.1252, but the principles are the same.

Occasionally it is useful to mix rules from several locales, e.g., use English collation rules but Spanish messages. To support that, a set of locale subcategories exist that control only certain aspects of the localization rules:

<table>
<thead>
<tr>
<th>Category</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>LC_COLLATE</td>
<td>String sort order</td>
</tr>
<tr>
<td>LC_CTYPE</td>
<td>Character classification (What is a letter? Its upper-case equivalent?)</td>
</tr>
<tr>
<td>LC_MESSAGES</td>
<td>Language of messages</td>
</tr>
<tr>
<td>LC_MONETARY</td>
<td>Formatting of currency amounts</td>
</tr>
<tr>
<td>LC_NUMERIC</td>
<td>Formatting of numbers</td>
</tr>
<tr>
<td>LC_TIME</td>
<td>Formatting of dates and times</td>
</tr>
</tbody>
</table>

The category names translate into names of initdb options to override the locale choice for a specific category. For instance, to set the locale to French Canadian, but use U.S. rules for formatting currency, use initdb --locale=fr_CA --lc-monetary=en_US.

If you want the system to behave as if it had no locale support, use the special locale name C, or equivalently POSIX.

Some locale categories must have their values fixed when the database is created. You can use different settings for different databases, but once a database is created, you cannot change them for that database anymore. LC_COLLATE and LC_CTYPE are these categories. They affect the sort order of indexes,
so they must be kept fixed, or indexes on text columns would become corrupt. (But you can alleviate this restriction using collations, as discussed in Section 22.2.) The default values for these categories are determined when initdb is run, and those values are used when new databases are created, unless specified otherwise in the CREATE DATABASE command.

The other locale categories can be changed whenever desired by setting the server configuration parameters that have the same name as the locale categories (see Section 18.11.2 for details). The values that are chosen by initdb are actually only written into the configuration file postgresql.conf to serve as defaults when the server is started. If you remove these assignments from postgresql.conf then the server will inherit the settings from its execution environment.

Note that the locale behavior of the server is determined by the environment variables seen by the server, not by the environment of any client. Therefore, be careful to configure the correct locale settings before starting the server. A consequence of this is that if client and server are set up in different locales, messages might appear in different languages depending on where they originated.

When we speak of inheriting the locale from the execution environment, this means the following on most operating systems: For a given locale category, say the collation, the following environment variables are consulted in this order until one is found to be set: LC_ALL, LC_COLLATE (or the variable corresponding to the respective category), LANG. If none of these environment variables are set then the locale defaults to C.

Some message localization libraries also look at the environment variable LANGUAGE which overrides all other locale settings for the purpose of setting the language of messages. If in doubt, please refer to the documentation of your operating system, in particular the documentation about gettext.

To enable messages to be translated to the user's preferred language, NLS must have been selected at build time (configure --enable-nls). All other locale support is built in automatically.

22.1.2. Behavior

The locale settings influence the following SQL features:

- Sort order in queries using ORDER BY or the standard comparison operators on textual data
- The upper, lower, and initcap functions
- Pattern matching operators (LIKE, SIMILAR TO, and POSIX-style regular expressions); locales affect both case insensitive matching and the classification of characters by character-class regular expressions
- The to_char family of functions
- The ability to use indexes with LIKE clauses

The drawback of using locales other than C or POSIX in Postgres Pro is its performance impact. It slows character handling and prevents ordinary indexes from being used by LIKE. For this reason use locales only if you actually need them.

As a workaround to allow Postgres Pro to use indexes with LIKE clauses under a non-C locale, several custom operator classes exist. These allow the creation of an index that performs a strict character-by-character comparison, ignoring locale comparison rules. Refer to Section 11.10 for more information. Another approach is to create indexes using the C collation, as discussed in Section 22.2.

22.1.3. Problems

If locale support doesn't work according to the explanation above, check that the locale support in your operating system is correctly configured. To check what locales are installed on your system, you can use the command locale -a if your operating system provides it.
Check that Postgres Pro is actually using the locale that you think it is. The `LC_COLLATE` and `LC_CTYPE` settings are determined when a database is created, and cannot be changed except by creating a new database. Other locale settings including `LC_MESSAGES` and `LC_MONETARY` are initially determined by the environment the server is started in, but can be changed on-the-fly. You can check the active locale settings using the `SHOW` command.

Client applications that handle server-side errors by parsing the text of the error message will obviously have problems when the server's messages are in a different language. Authors of such applications are advised to make use of the error code scheme instead.

### 22.2. Collation Support

The collation feature allows specifying the sort order and character classification behavior of data per-column, or even per-operation. This alleviates the restriction that the `LC_COLLATE` and `LC_CTYPE` settings of a database cannot be changed after its creation.

#### 22.2.1. Concepts

Conceptually, every expression of a collatable data type has a collation. (The built-in collatable data types are `text`, `varchar`, and `char`. User-defined base types can also be marked collatable, and of course a domain over a collatable data type is collatable.) If the expression is a column reference, the collation of the expression is the defined collation of the column. If the expression is a constant, the collation is the default collation of the data type of the constant. The collation of a more complex expression is derived from the collations of its inputs, as described below.

The collation of an expression can be the “default” collation, which means the locale settings defined for the database. It is also possible for an expression's collation to be indeterminate. In such cases, ordering operations and other operations that need to know the collation will fail.

When the database system has to perform an ordering or a character classification, it uses the collation of the input expression. This happens, for example, with `ORDER BY` clauses and function or operator calls such as `<`. The collation to apply for an `ORDER BY` clause is simply the collation of the sort key. The collation to apply for a function or operator call is derived from the arguments, as described below. In addition to comparison operators, collations are taken into account by functions that convert between lower and upper case letters, such as `lower`, `upper`, and `initcap`; by pattern matching operators; and by `to_char` and related functions.

For a function or operator call, the collation that is derived by examining the argument collations is used at run time for performing the specified operation. If the result of the function or operator call is of a collatable data type, the collation is also used at parse time as the defined collation of the function or operator expression, in case there is a surrounding expression that requires knowledge of its collation.

The **collation derivation** of an expression can be implicit or explicit. This distinction affects how collations are combined when multiple different collations appear in an expression. An explicit collation derivation occurs when a `COLLATE` clause is used; all other collation derivations are implicit. When multiple collations need to be combined, for example in a function call, the following rules are used:

1. If any input expression has an explicit collation derivation, then all explicitly derived collations among the input expressions must be the same, otherwise an error is raised. If any explicitly derived collation is present, that is the result of the collation combination.

2. Otherwise, all input expressions must have the same implicit collation derivation or the default collation. If any non-default collation is present, that is the result of the collation combination. Otherwise, the result is the default collation.

3. If there are conflicting non-default implicit collations among the input expressions, then the combination is deemed to have indeterminate collation. This is not an error condition unless the particular function being invoked requires knowledge of the collation it should apply. If it does, an error will be raised at run-time.

For example, consider this table definition:
CREATE TABLE test1 (  
a text COLLATE "ru_RU",
b text COLLATE "es_ES",
...
);

Then in
SELECT a < 'foo' FROM test1;
the < comparison is performed according to ru_RU rules, because the expression combines an implicitly derived collation with the default collation. But in
SELECT a < ('foo' COLLATE "fr_FR") FROM test1;
the comparison is performed using fr_FR rules, because the explicit collation derivation overrides the implicit one. Furthermore, given
SELECT a < b FROM test1;
the parser cannot determine which collation to apply, since the a and b columns have conflicting implicit collations. Since the < operator does need to know which collation to use, this will result in an error. The error can be resolved by attaching an explicit collation specifier to either input expression, thus:
SELECT a < b COLLATE "ru_RU" FROM test1;
or equivalently
SELECT a COLLATE "ru_RU" < b FROM test1;
On the other hand, the structurally similar case
SELECT a || b FROM test1;
does not result in an error, because the || operator does not care about collations: its result is the same regardless of the collation.

The collation assigned to a function or operator's combined input expressions is also considered to apply to the function or operator's result, if the function or operator delivers a result of a collatable data type. So, in
SELECT * FROM test1 ORDER BY a || 'foo';
the ordering will be done according to ru_RU rules. But this query:
SELECT * FROM test1 ORDER BY a || b;
results in an error, because even though the || operator doesn't need to know a collation, the ORDER BY clause does. As before, the conflict can be resolved with an explicit collation specifier:
SELECT * FROM test1 ORDER BY a || b COLLATE "fr_FR";

22.2.2. Managing Collations

A collation is an SQL schema object that maps an SQL name to locales provided by libraries installed in the operating system. A collation definition has a provider that specifies which library supplies the locale data. One standard provider name is libc, which uses the locales provided by the operating system C library. These are the locales that most tools provided by the operating system use. Another provider is icu, which uses the external ICU library. ICU locales can only be used if support for ICU was configured when Postgres Pro was built.

A collation object provided by libc maps to a combination of LC_COLLATE and LC_CTYPE settings, as accepted by the setlocale() system library call. (As the name would suggest, the main purpose of a collation is to set LC_COLLATE, which controls the sort order. But it is rarely necessary in practice to have an LC_CTYPE setting that is different from LC_COLLATE, so it is more convenient to collect these under one concept than to create another infrastructure for setting LC_CTYPE per expression.) Also, a libc collation is tied to a character set encoding (see Section 22.3). The same collation name may exist for different encodings.
Localization

A collation object provided by icu maps to a named collator provided by the ICU library. ICU does not support separate “collate” and “ctype” settings, so they are always the same. Also, ICU collations are independent of the encoding, so there is always only one ICU collation of a given name in a database.

You can specify the provider of the default collation with the --locale and --lc-collate options of the initdb or createdb commands, as follows:

```
--locale=locale[@provider]
--lc-collate=locale[@provider]
```

where provider can take the icu or libc value, and locale is specified in the libc format. You can only specify a single locale provider after the @ symbol. The --lc-collate option overrides the --locale setting, regardless of whether the collation provider is specified.

If you do not specify the provider, libc is used for C and POSIX locales. For other locales, the default provider is:

- icu at the cluster level
- Provider of the default collation from the template database at the database level

**Important**

You can only use the icu collation provider for locales that are supported by libc in your operating system and satisfy all restrictions applicable to icu.

Before starting the server, Postgres Pro checks that the cluster was initialized by a server compiled with the same version of ICU, even if icu is not used as the provider for the default collation. If the ICU library versions do not match, Postgres Pro emits the appropriate informational message.

Before connecting to a database with an icu default collation, Postgres Pro compares this collation version to the one provided by the ICU library. If the collation version changes, you may need to rebuild the objects that depend on a changed collation if you think this change may affect the sort order of your data. Postgres Pro displays a warning if collation versions do not match, or it is impossible to compare them because the cluster does not provide any information about the collation version for the default collation. To suppress these warnings, you can use the ALTER COLLATION "default" REFRESH VERSION command, as explained in ALTER COLLATION.

You can find the default collation and its provider in pg_database.datcollate:

```
locale@provider
```

### 22.2.2.1. Standard Collations

On all platforms, the collations named default, C, and POSIX are available. Additional collations may be available depending on operating system support. The default collation selects the LC_COLLATE and LC_CTYPE values specified at database creation time. The C and POSIX collations both specify “traditional C” behavior, in which only the ASCII letters “A” through “Z” are treated as letters, and sorting is done strictly by character code byte values.

Additionally, the SQL standard collation name ucs_basic is available for encoding UTF8. It is equivalent to C and sorts by Unicode code point.

### 22.2.2.2. Predefined Collations

If the operating system provides support for using multiple locales within a single program (newlocale and related functions), or if support for ICU is configured, then when a database cluster is initialized, initdb populates the system catalog pg_collation with collations based on all the locales it finds in the operating system at the time.

To inspect the currently available locales, use the query SELECT * FROM pg_collation, or the command \dOS+ in psql.
### 22.2.2.2.1. libc Collations

For example, the operating system might provide a locale named `ru_RU.utf8`. `initdb` would then create a collation named `ru_RU.utf8` for encoding UTF8 that has both `LC_COLLATE` and `LC_CTYPE` set to `ru_RU.utf8`. It will also create a collation with the `.utf8` tag stripped off the name. So you could also use the collation under the name `ru_RU`, which is less cumbersome to write and makes the name less encoding-dependent. Note that, nevertheless, the initial set of collation names is platform-dependent.

The default set of collations provided by `libc` map directly to the locales installed in the operating system, which can be listed using the command `locale -a`. In case a `libc` collation is needed that has different values for `LC_COLLATE` and `LC_CTYPE`, or if new locales are installed in the operating system after the database system was initialized, then a new collation may be created using the `CREATE COLLATION` command. New operating system locales can also be imported en masse using the `pg_import_system_collations()` function.

Within any particular database, only collations that use that database's encoding are of interest. Other entries in `pg_collation` are ignored. Thus, a stripped collation name such as `ru_RU` can be considered unique within a given database even though it would not be unique globally. Use of the stripped collation names is recommended, since it will make one fewer thing you need to change if you decide to change to another database encoding. Note however that the default, `C`, and `POSIX` collations can be used regardless of the database encoding.

Postgres Pro considers distinct collation objects to be incompatible even when they have identical properties. Thus for example,

```
SELECT a COLLATE "C" < b COLLATE "POSIX" FROM test1;
```

will draw an error even though the `C` and `POSIX` collations have identical behaviors. Mixing stripped and non-stripped collation names is therefore not recommended.

### 22.2.2.2. ICU Collations

With ICU, it is not sensible to enumerate all possible locale names. ICU uses a particular naming system for locales, but there are many more ways to name a locale than there are actually distinct locales. `initdb` uses the ICU APIs to extract a set of distinct locales to populate the initial set of collations. Collations provided by ICU are created in the SQL environment with names in BCP 47 language tag format, with a “private use” extension `-x-icu` appended, to distinguish them from `libc` locales.

Here are some example collations that might be created:

- `ru-x-icu`
  - Russian collation, default variant
- `ru-UA-x-icu`
  - Russian collation for Ukraine, default variant

  (There is also, say, `ru-RU-x-icu`, but as of this writing, it is equivalent to `ru-x-icu`.)

- `und-x-icu` (for “undefined”)
  - ICU “root” collation. Use this to get a reasonable language-agnostic sort order.

Some (less frequently used) encodings are not supported by ICU. When the database encoding is one of these, ICU collation entries in `pg_collation` are ignored. Attempting to use one will draw an error along the lines of “collation "de-x-icu" for encoding "WIN874" does not exist”.

### 22.2.2.3. Creating New Collation Objects

If the standard and predefined collations are not sufficient, users can create their own collation objects using the SQL command `CREATE COLLATION`.

The standard and predefined collations are in the schema `pg_catalog`, like all predefined objects. User-defined collations should be created in user schemas. This also ensures that they are saved by `pg_dump`.
22.2.2.3.1. libc Collations

New libc collations can be created like this:

CREATE COLLATION russian (provider = libc, locale = 'ru_RU');

The exact values that are acceptable for the locale clause in this command depend on the operating system. On Unix-like systems, the command `locale -a` will show a list.

Since the predefined libc collations already include all collations defined in the operating system when the database instance is initialized, it is not often necessary to manually create new ones. Reasons might be if a different naming system is desired (in which case see also Section 22.2.2.3.3) or if the operating system has been upgraded to provide new locale definitions (in which case see also `pg_import_system_collations()`).

22.2.2.3.2. ICU Collations

ICU allows collations to be customized beyond the basic language+country set that is preloaded by `initdb`. Users are encouraged to define their own collation objects that make use of these facilities to suit the sorting behavior to their requirements. See https://unicode-org.github.io/icu/userguide/locale/ and https://unicode-org.github.io/icu/userguide/collation/api.html for information on ICU locale naming.

The set of acceptable names and attributes depends on the particular ICU version.

Here are some examples:

CREATE COLLATION "de-u-co-phonebk-x-icu" (provider = icu, locale = 'de-u-co-phonebk');
CREATE COLLATION "de-u-co-phonebk-x-icu" (provider = icu, locale = 'de@collation=phonebook');

German collation with phone book collation type

The first example selects the ICU locale using a “language tag” per BCP 47. The second example uses the traditional ICU-specific locale syntax. The first style is preferred going forward, but it is not supported by older ICU versions.

Note that you can name the collation objects in the SQL environment anything you want. In this example, we follow the naming style that the predefined collations use, which in turn also follow BCP 47, but that is not required for user-defined collations.

CREATE COLLATION "und-u-co-emoji-x-icu" (provider = icu, locale = 'und-u-co-emoji');
CREATE COLLATION "und-u-co-emoji-x-icu" (provider = icu, locale = '@collation=emoji');

Root collation with Emoji collation type, per Unicode Technical Standard #51

Observe how in the traditional ICU locale naming system, the root locale is selected by an empty string.

CREATE COLLATION latn_cyril (provider = icu, locale = 'ru-RU-kr-latn-cyril');
CREATE COLLATION latn_cyril (provider = icu, locale = 'ru@colReorder=latn-cyril');

Sort Latin letters before Cyrillic ones. (The default is Cyrillic before Latin.)

CREATE COLLATION upperfirst (provider = icu, locale = 'ru-RU-uf-upper');
CREATE COLLATION upperfirst (provider = icu, locale = 'ru@colCaseFirst=upper');

Sort upper-case letters before lower-case letters. (The default is lower-case letters first.)

CREATE COLLATION special (provider = icu, locale = 'ru-RU-u-kr-upper-latn-cyril');
CREATE COLLATION special (provider = icu, locale = 'ru@colCaseFirst=upper;colReorder=latn-cyril');

Combines both of the above options.

CREATE COLLATION numeric (provider = icu, locale = 'en-u-kn-true');
CREATE COLLATION numeric (provider = icu, locale = 'en@colNumeric=yes');

Numeric ordering, sorts sequences of digits by their numeric value, for example: A–21 < A–123 (also known as natural sort).
See *Unicode Technical Standard #35* and *BCP 47* for details. The list of possible collation types (co subtag) can be found in the *CLDR repository*.

Note that while this system allows creating collations that “ignore case” or “ignore accents” or similar (using the ks key), in order for such collations to act in a truly case- or accent-insensitive manner, they also need to be declared as not deterministic in *CREATE COLLATION*; see Section 22.2.2.4. Otherwise, any strings that compare equal according to the collation but are not byte-wise equal will be sorted according to their byte values.

**Note**

By design, ICU will accept almost any string as a locale name and match it to the closest locale it can provide, using the fallback procedure described in its documentation. Thus, there will be no direct feedback if a collation specification is composed using features that the given ICU installation does not actually support. It is therefore recommended to create application-level test cases to check that the collation definitions satisfy one's requirements.

### 22.2.2.3.3. Copying Collations

The command *CREATE COLLATION* can also be used to create a new collation from an existing collation, which can be useful to be able to use operating-system-independent collation names in applications, create compatibility names, or use an ICU-provided collation under a more readable name. For example:

```
CREATE COLLATION russian FROM "ru_RU";
CREATE COLLATION french FROM "fr-x-icu";
```

### 22.2.2.4. Nondeterministic Collations

A collation is either deterministic or nondeterministic. A deterministic collation uses deterministic comparisons, which means that it considers strings to be equal only if they consist of the same byte sequence. Nondeterministic comparison may determine strings to be equal even if they consist of different bytes. Typical situations include case-insensitive comparison, accent-insensitive comparison, as well as comparison of strings in different Unicode normal forms. It is up to the collation provider to actually implement such insensitive comparisons; the deterministic flag only determines whether ties are to be broken using bytewise comparison. See also *Unicode Technical Standard 10* for more information on the terminology.

To create a nondeterministic collation, specify the property deterministic = false to *CREATE COLLATION*, for example:

```
CREATE COLLATION ndcoll (provider = icu, locale = 'und', deterministic = false);
```

This example would use the standard Unicode collation in a nondeterministic way. In particular, this would allow strings in different normal forms to be compared correctly. More interesting examples make use of the ICU customization facilities explained above. For example:

```
CREATE COLLATION case_insensitive (provider = icu, locale = 'und-u-ks-level2',
  deterministic = false);
CREATE COLLATION ignore_accents (provider = icu, locale = 'und-u-ks-level1-kc-true',
  deterministic = false);
```

All standard and predefined collations are deterministic, all user-defined collations are deterministic by default. While nondeterministic collations give a more “correct” behavior, especially when considering the full power of Unicode and its many special cases, they also have some drawbacks. Foremost, their use leads to a performance penalty. Note, in particular, that B-tree cannot use deduplication with indexes that use a nondeterministic collation. Also, certain operations are not possible with nondeterministic collations, such as pattern matching operations. Therefore, they should be used only in cases where they are specifically wanted.
Tip
To deal with text in different Unicode normalization forms, it is also an option to use the functions/expressions `normalize` and `is_normalized` to preprocess or check the strings, instead of using nondeterministic collations. There are different trade-offs for each approach.

22.3. Character Set Support
The character set support in Postgres Pro allows you to store text in a variety of character sets (also called encodings), including single-byte character sets such as the ISO 8859 series and multiple-byte character sets such as EUC (Extended Unix Code), UTF-8, and Mule internal code. All supported character sets can be used transparently by clients, but a few are not supported for use within the server (that is, as a server-side encoding). The default character set is selected while initializing your Postgres Pro database cluster using `initdb`. It can be overridden when you create a database, so you can have multiple databases each with a different character set.

An important restriction, however, is that each database's character set must be compatible with the database's `LC_CTYPE` (character classification) and `LC_COLLATE` (string sort order) locale settings. For C or POSIX locale, any character set is allowed, but for other libc-provided locales there is only one character set that will work correctly. (On Windows, however, UTF-8 encoding can be used with any locale.) If you have ICU support configured, ICU-provided locales can be used with most but not all server-side encodings.

22.3.1. Supported Character Sets
Table 22.1 shows the character sets available for use in Postgres Pro.

</tbody>
</table>

Not all client APIs support all the listed character sets. For example, the Postgres Pro JDBC driver does not support MULE_INTERNAL, LATIN6, LATIN8, and LATIN10.

The SQL_ASCII setting behaves considerably differently from the other settings. When the server character set is SQL_ASCII, the server interprets byte values 0–127 according to the ASCII standard, while byte values 128–255 are taken as uninterpreted characters. No encoding conversion will be done when the setting is SQL_ASCII. Thus, this setting is not so much a declaration that a specific encoding is in use, as a declaration of ignorance about the encoding. In most cases, if you are working with any non-ASCII data, it is unwise to use the SQL_ASCII setting because Postgres Pro will be unable to help you by converting or validating non-ASCII characters.

#### 22.3.2. Setting the Character Set

`initdb` defines the default character set (encoding) for a Postgres Pro cluster. For example,

```bash
initdb -E EUC_JP
```

sets the default character set to EUC_JP (Extended Unix Code for Japanese). You can use `--encoding` instead of `-E` if you prefer longer option strings. If no `-E` or `--encoding` option is given, `initdb` attempts to determine the appropriate encoding to use based on the specified or default locale.

You can specify a non-default encoding at database creation time, provided that the encoding is compatible with the selected locale:

```bash
createdb -E EUC_KR -T template0 --lc-collate=ko_KR.euckr --lc-ctype=ko_KR.euckr korean
```

This will create a database named korean that uses the character set EUC_KR, and locale ko_KR. Another way to accomplish this is to use this SQL command:

```sql
CREATE DATABASE korean WITH ENCODING 'EUC_KR' LC_COLLATE='ko_KR.euckr' LC_CTYPE='ko_KR.euckr' TEMPLATE=template0;
```

Notice that the above commands specify copying the template0 database. When copying any other database, the encoding and locale settings cannot be changed from those of the source database, because that might result in corrupt data. For more information see Section 21.3.
The encoding for a database is stored in the system catalog `pg_database`. You can see it by using the `psql -l` option or the `\l` command.

```
$ psql -l
```

### Important

On most modern operating systems, Postgres Pro can determine which character set is implied by the `LC_CTYPE` setting, and it will enforce that only the matching database encoding is used. On older systems it is your responsibility to ensure that you use the encoding expected by the locale you have selected. A mistake in this area is likely to lead to strange behavior of locale-dependent operations such as sorting.

Postgres Pro will allow superusers to create databases with `SQL_ASCII` encoding even when `LC_CTYPE` is not `C` or `POSIX`. As noted above, `SQL_ASCII` does not enforce that the data stored in the database has any particular encoding, and so this choice poses risks of locale-dependent misbehavior. Using this combination of settings is deprecated and may someday be forbidden altogether.

### 22.3.3. Automatic Character Set Conversion Between Server and Client

Postgres Pro supports automatic character set conversion between server and client for many combinations of character sets ([Section 22.3.4](#) shows which ones).

To enable automatic character set conversion, you have to tell Postgres Pro the character set (encoding) you would like to use in the client. There are several ways to accomplish this:

- **Using the \encoding command in psql.** \encoding allows you to change client encoding on the fly. For example, to change the encoding to `SJIS`, type:
  
  \encoding SJIS

- **libpq ([Section 32.11](#))** has functions to control the client encoding.

- **Using SET client_encoding TO.** Setting the client encoding can be done with this SQL command:
  
  ```sql
  SET CLIENT_ENCODING TO 'value';
  ```
  
  Also you can use the standard SQL syntax `SET NAMES` for this purpose:
  
  ```sql
  SET NAMES 'value';
  ```
  
  To query the current client encoding:
  
  ```sql
  SHOW client_encoding;
  ```
  
  To return to the default encoding:
RESET client_encoding;

- **Using `PGCLIENTENCODING`**. If the environment variable `PGCLIENTENCODING` is defined in the client's environment, that client encoding is automatically selected when a connection to the server is made. (This can subsequently be overridden using any of the other methods mentioned above.)

- **Using the configuration variable `client_encoding`**. If the `client_encoding` variable is set, that client encoding is automatically selected when a connection to the server is made. (This can subsequently be overridden using any of the other methods mentioned above.)

If the conversion of a particular character is not possible — suppose you chose `EUC_JP` for the server and `LATIN1` for the client, and some Japanese characters are returned that do not have a representation in `LATIN1` — an error is reported.

If the client character set is defined as `SQL_ASCII`, encoding conversion is disabled, regardless of the server's character set. (However, if the server's character set is not `SQL_ASCII`, the server will still check that incoming data is valid for that encoding; so the net effect is as though the client character set were the same as the server's.) Just as for the server, use of `SQL_ASCII` is unwise unless you are working with all-ASCII data.

### 22.3.4. Available Character Set Conversions

PostgreSQL allows conversion between any two character sets for which a conversion function is listed in the `pg_conversion` system catalog. PostgreSQL comes with some predefined conversions, as summarized in Table 22.2 and shown in more detail in Table 22.3. You can create a new conversion using the SQL command `CREATE CONVERSION`. (To be used for automatic client/server conversions, a conversion must be marked as “default” for its character set pair.)

*a The conversion names follow a standard naming scheme: The official name of the source encoding with all non-alphanumeric characters replaced by underscores, followed by _to_ followed by the similarly processed destination encoding name. Therefore, these names sometimes deviate from the customary encoding names shown in Table 22.1.

Chapter 23. Routine Database Maintenance Tasks

Postgres Pro, like any database software, requires that certain tasks be performed regularly to achieve optimum performance. The tasks discussed here are required, but they are repetitive in nature and can easily be automated using standard tools such as cron scripts or Windows’ Task Scheduler. It is the database administrator’s responsibility to set up appropriate scripts, and to check that they execute successfully.

One obvious maintenance task is the creation of backup copies of the data on a regular schedule. Without a recent backup, you have no chance of recovery after a catastrophe (disk failure, fire, mistakenly dropping a critical table, etc.). The backup and recovery mechanisms available in Postgres Pro are discussed at length in Chapter 24.

The other main category of maintenance task is periodic “vacuuming” of the database. This activity is discussed in Section 23.1. Closely related to this is updating the statistics that will be used by the query planner, as discussed in Section 23.1.3.

Another task that might need periodic attention is log file management. This is discussed in Section 23.3. check_postgres is available for monitoring database health and reporting unusual conditions. check_postgres integrates with Nagios and MRTG, but can be run standalone too.

Postgres Pro is low-maintenance compared to some other database management systems. Nonetheless, appropriate attention to these tasks will go far towards ensuring a pleasant and productive experience with the system.

23.1. Routine Vacuuming

Postgres Pro databases require periodic maintenance known as vacuuming. For many installations, it is sufficient to let vacuuming be performed by the autovacuum daemon, which is described in Section 23.1.6. You might need to adjust the autovacuuming parameters described there to obtain best results for your situation. Some database administrators will want to supplement or replace the daemon’s activities with manually-managed VACUUM commands, which typically are executed according to a schedule by cron or Task Scheduler scripts. To set up manually-managed vacuuming properly, it is essential to understand the issues discussed in the next few subsections. Administrators who rely on autovacuuming may still wish to skim this material to help them understand and adjust autovacuuming.

23.1.1. Vacuuming Basics

Postgres Pro’s VACUUM command has to process each table on a regular basis for several reasons:

1. To recover or reuse disk space occupied by updated or deleted rows.
2. To update data statistics used by the Postgres Pro query planner.
3. To update the visibility map, which speeds up index-only scans.
4. To protect against loss of very old data due to transaction ID wraparound or multixact ID wraparound.

Each of these reasons dictates performing VACUUM operations of varying frequency and scope, as explained in the following subsections.

There are two variants of VACUUM: standard VACUUM and VACUUM FULL. VACUUM FULL can reclaim more disk space but runs much more slowly. Also, the standard form of VACUUM can run in parallel with production database operations. (Commands such as SELECT, INSERT, UPDATE, and DELETE will continue to function normally, though you will not be able to modify the definition of a table with commands such as ALTER TABLE while it is being vacuumed.) VACUUM FULL requires an ACCESS EXCLUSIVE lock on the table it is
Routine Database
Maintenance Tasks

working on, and therefore cannot be done in parallel with other use of the table. Generally, therefore, administrators should strive to use standard VACUUM and avoid VACUUM FULL.

VACUUM creates a substantial amount of I/O traffic, which can cause poor performance for other active sessions. There are configuration parameters that can be adjusted to reduce the performance impact of background vacuuming — see Section 18.4.4.

23.1.2. Recovering Disk Space

In Postgres Pro, an UPDATE or DELETE of a row does not immediately remove the old version of the row. This approach is necessary to gain the benefits of multiversion concurrency control (MVCC, see Chapter 13): the row version must not be deleted while it is still potentially visible to other transactions. But eventually, an outdated or deleted row version is no longer of interest to any transaction. The space it occupies must then be reclaimed for reuse by new rows, to avoid unbounded growth of disk space requirements. This is done by running VACUUM.

The standard form of VACUUM removes dead row versions in tables and indexes and marks the space available for future reuse. However, it will not return the space to the operating system, except in the special case where one or more pages at the end of a table become entirely free and an exclusive table lock can be easily obtained. In contrast, VACUUM FULL actively compacts tables by writing a complete new version of the table file with no dead space. This minimizes the size of the table, but can take a long time. It also requires extra disk space for the new copy of the table, until the operation completes.

The usual goal of routine vacuuming is to do standard VACUUMs often enough to avoid needing VACUUM FULL. The autovacuum daemon attempts to work this way, and in fact will never issue VACUUM FULL. In this approach, the idea is not to keep tables at their minimum size, but to maintain steady-state usage of disk space: each table occupies space equivalent to its minimum size plus however much space gets used up between vacuum runs. Although VACUUM FULL can be used to shrink a table back to its minimum size and return the disk space to the operating system, there is not much point in this if the table will just grow again in the future. Thus, moderately-frequent standard VACUUM runs are a better approach than infrequent VACUUM FULL runs for maintaining heavily-updated tables.

Some administrators prefer to schedule vacuuming themselves, for example doing all the work at night when load is low. The difficulty with doing vacuuming according to a fixed schedule is that if a table has an unexpected spike in update activity, it may get bloated to the point that VACUUM FULL is really necessary to reclaim space. Using the autovacuum daemon alleviates this problem, since the daemon schedules vacuuming dynamically in response to update activity. It is unwise to disable the daemon completely unless you have an extremely predictable workload. One possible compromise is to set the daemon's parameters so that it will only react to unusually heavy update activity, thus keeping things from getting out of hand, while scheduled VACUUMs are expected to do the bulk of the work when the load is typical.

For those not using autovacuum, a typical approach is to schedule a database-wide VACUUM once a day during a low-usage period, supplemented by more frequent vacuuming of heavily-updated tables as necessary. (Some installations with extremely high update rates vacuum their busiest tables as often as once every few minutes.) If you have multiple databases in a cluster, don't forget to VACUUM each one; the program vacuumdb might be helpful.

Tip

Plain VACUUM may not be satisfactory when a table contains large numbers of dead row versions as a result of massive update or delete activity. If you have such a table and you need to reclaim the excess disk space it occupies, you will need to use VACUUM FULL, or alternatively CLUSTER or one of the table-rewriting variants of ALTER TABLE. These commands rewrite an entire new copy of the table and build new indexes for it. All these options require an ACCESS EXCLUSIVE lock. Note that they also temporarily use extra disk space approximately equal to the size of the table, since the old copies of the table and indexes can't be released until the new ones are complete.
Routine Database
Maintenance Tasks

Tip
If you have a table whose entire contents are deleted on a periodic basis, consider doing it with \texttt{TRUNCATE} rather than using \texttt{DELETE} followed by \texttt{VACUUM}. \texttt{TRUNCATE} removes the entire content of the table immediately, without requiring a subsequent \texttt{VACUUM} or \texttt{VACUUM FULL} to reclaim the now-unused disk space. The disadvantage is that strict MVCC semantics are violated.

23.1.3. Updating Planner Statistics

The Postgres Pro query planner relies on statistical information about the contents of tables in order to generate good plans for queries. These statistics are gathered by the \texttt{ANALYZE} command, which can be invoked by itself or as an optional step in \texttt{VACUUM}. It is important to have reasonably accurate statistics, otherwise poor choices of plans might degrade database performance.

The autovacuum daemon, if enabled, will automatically issue \texttt{ANALYZE} commands whenever the content of a table has changed sufficiently. However, administrators might prefer to rely on manually-scheduled \texttt{ANALYZE} operations, particularly if it is known that update activity on a table will not affect the statistics of “interesting” columns. The daemon schedules \texttt{ANALYZE} strictly as a function of the number of rows inserted or updated; it has no knowledge of whether that will lead to meaningful statistical changes.

As with vacuuming for space recovery, frequent updates of statistics are more useful for heavily-updated tables than for seldom-updated ones. But even for a heavily-updated table, there might be no need for statistics updates if the statistical distribution of the data is not changing much. A simple rule of thumb is to think about how much the minimum and maximum values of the columns in the table change. For example, a \texttt{timestamp} column that contains the time of row update will have a constantly-increasing maximum value as rows are added and updated; such a column will probably need more frequent statistics updates than, say, a column containing URLs for pages accessed on a website. The URL column might receive changes just as often, but the statistical distribution of its values probably changes relatively slowly.

It is possible to run \texttt{ANALYZE} on specific tables and even just specific columns of a table, so the flexibility exists to update some statistics more frequently than others if your application requires it. In practice, however, it is usually best to just analyze the entire database, because it is a fast operation. \texttt{ANALYZE} uses a statistically random sampling of the rows of a table rather than reading every single row.

Tip
Although per-column tweaking of \texttt{ANALYZE} frequency might not be very productive, you might find it worthwhile to do per-column adjustment of the level of detail of the statistics collected by \texttt{ANALYZE}. Columns that are heavily used in \texttt{WHERE} clauses and have highly irregular data distributions might require a finer-grain data histogram than other columns. See \texttt{ALTER TABLE SET STATISTICS}, or change the database-wide default using the \texttt{default_statistics_target} configuration parameter.

Also, by default there is limited information available about the selectivity of functions. However, if you create a statistics object or an expression index that uses a function call, useful statistics will be gathered about the function, which can greatly improve query plans that use the expression index.

Tip
The autovacuum daemon does not issue \texttt{ANALYZE} commands for foreign tables, since it has no means of determining how often that might be useful. If your queries require statistics on foreign
Routine Database
Maintenance Tasks

23.1.4. Updating the Visibility Map

Vacuum maintains a visibility map for each table to keep track of which pages contain only tuples that are known to be visible to all active transactions (and all future transactions, until the page is again modified). This has two purposes. First, vacuum itself can skip such pages on the next run, since there is nothing to clean up.

Second, it allows Postgres Pro to answer some queries using only the index, without reference to the underlying table. Since Postgres Pro indexes don't contain tuple visibility information, a normal index scan fetches the heap tuple for each matching index entry, to check whether it should be seen by the current transaction. An index-only scan, on the other hand, checks the visibility map first. If it's known that all tuples on the page are visible, the heap fetch can be skipped. This is most useful on large data sets where the visibility map can prevent disk accesses. The visibility map is vastly smaller than the heap, so it can easily be cached even when the heap is very large.

23.1.5. Preventing Transaction ID Wraparound Failures

Postgres Pro's MVCC transaction semantics depend on being able to compare transaction ID (XID) numbers: a row version with an insertion XID greater than the current transaction's XID is “in the future” and should not be visible to the current transaction. But since transaction IDs have limited size (32 bits) a cluster that runs for a long time (more than 4 billion transactions) would suffer transaction ID wraparound: the XID counter wraps around to zero, and all of a sudden transactions that were in the past appear to be in the future — which means their output become invisible. In short, catastrophic data loss. (Actually the data is still there, but that’s cold comfort if you cannot get at it.) To avoid this, it is necessary to vacuum every table in every database at least once every two billion transactions.

The reason that periodic vacuuming solves the problem is that VACUUM will mark rows as frozen, indicating that they were inserted by a transaction that committed sufficiently far in the past that the effects of the inserting transaction are certain to be visible to all current and future transactions. Normal XIDs are compared using modulo-2^32 arithmetic. This means that for every normal XID, there are two billion XIDs that are “older” and two billion that are “newer”; another way to say it is that the normal XID space is circular with no endpoint. Therefore, once a row version has been created with a particular normal XID, the row version will appear to be “in the past” for the next two billion transactions, no matter which normal XID we are talking about. If the row version still exists after more than two billion transactions, it will suddenly appear to be in the future. To prevent this, Postgres Pro reserves a special XID, FrozenTransactionId, which does not follow the normal XID comparison rules and is always considered older than every normal XID. Frozen row versions are treated as if the inserting XID were FrozenTransactionId, so that they will appear to be “in the past” to all normal transactions regardless of wraparound issues, and so such row versions will be valid until deleted, no matter how long that is.

Note

In PostgreSQL versions before 9.4, freezing was implemented by actually replacing a row's insertion XID with FrozenTransactionId, which was visible in the row's xmin system column. Newer versions just set a flag bit, preserving the row's original xmin for possible forensic use. However, rows with xmin equal to FrozenTransactionId (2) may still be found in databases pg_upgrade'd from pre-9.4 versions.

Also, system catalogs may contain rows with xmin equal to BootstrapTransactionId (1), indicating that they were inserted during the first phase of initdb. Like FrozenTransactionId, this special XID is treated as older than every normal XID.

vacuum_freeze_min_age controls how old an XID value has to be before rows bearing that XID will be frozen. Increasing this setting may avoid unnecessary work if the rows that would otherwise be frozen...
will soon be modified again, but decreasing this setting increases the number of transactions that can elapse before the table must be vacuumed again.

VACUUM uses the visibility map to determine which pages of a table must be scanned. Normally, it will skip pages that don't have any dead row versions even if those pages might still have row versions with old XID values. Therefore, normal VACUUM won't always freeze every old row version in the table. Periodically, VACUUM will perform an aggressive vacuum, skipping only those pages which contain neither dead rows nor any unfrozen XID or MXID values. vacuum_freeze_table_age controls when VACUUM does that: all-visible but not all-frozen pages are scanned if the number of transactions that have passed since the last such scan is greater than vacuum_freeze_table_age minus vacuum_freeze_min_age. Setting vacuum_freeze_table_age to 0 forces VACUUM to use this more aggressive strategy for all scans.

The maximum time that a table can go unvacuumed is two billion transactions minus the vacuum_freeze_min_age value at the time of the last aggressive vacuum. If it were to go unvacuumed for longer than that, data loss could result. To ensure that this does not happen, autovacuum is invoked on any table that might contain unfrozen rows with XIDs older than the age specified by the configuration parameter autovacuum_freeze_max_age. (This will happen even if autovacuum is disabled.)

This implies that if a table is not otherwise vacuumed, autovacuum will be invoked on it approximately once every autovacuum_freeze_max_age minus vacuum_freeze_min_age transactions. For tables that are regularly vacuumed for space reclamation purposes, this is of little importance. However, for static tables (including tables that receive inserts, but no updates or deletes), there is no need to vacuum for space reclamation, so it can be useful to try to maximize the interval between forced autovacuums on very large static tables. Obviously one can do this either by increasing autovacuum_freeze_max_age or decreasing vacuum_freeze_min_age.

The effective maximum for vacuum_freeze_table_age is 0.95 * autovacuum_freeze_max_age; a setting higher than that will be capped to the maximum. A value higher than autovacuum_freeze_max_age wouldn't make sense because an anti-wraparound autovacuum would be triggered at that point anyway, and the 0.95 multiplier leaves some breathing room to run a manual VACUUM before that happens. As a rule of thumb, vacuum_freeze_table_age should be set to a value somewhat below autovacuum_freeze_max_age, leaving enough gap so that a regularly scheduled VACUUM or an autovacuum triggered by normal delete and update activity is run in that window. Setting it too close could lead to anti-wraparound autovacuums, even though the table was recently vacuumed to reclaim space, whereas lower values lead to more frequent aggressive vacuuming.

The sole disadvantage of increasing autovacuum_freeze_max_age (and vacuum_freeze_table_age along with it) is that the pg_xact and pg_commit_ts subdirectories of the database cluster will take more space, because it must store the commit status and (if track_commit_timestamp is enabled) timestamp of all transactions back to the autovacuum_freeze_max_age horizon. The commit status uses two bits per transaction, so if autovacuum_freeze_max_age is set to its maximum allowed value of two billion, pg_xact can be expected to grow to about half a gigabyte and pg_commit_ts to about 20GB. If this is trivial compared to your total database size, setting autovacuum_freeze_max_age to its maximum allowed value is recommended. Otherwise, set it depending on what you are willing to allow for pg_xact and pg_commit_ts storage. (The default, 200 million transactions, translates to about 50MB of pg_xact storage and about 2GB of pg_commit_ts storage.)

One disadvantage of decreasing vacuum_freeze_min_age is that it might cause VACUUM to do useless work: freezing a row version is a waste of time if the row is modified soon thereafter (causing it to acquire a new XID). So the setting should be large enough that rows are not frozen until they are unlikely to change any more.

To track the age of the oldest unfrozen XIDs in a database, VACUUM stores XID statistics in the system tables pg_class and pg_database. In particular, the relfrozenxid column of a table's pg_class row contains the freeze cutoff XID that was used by the last aggressive VACUUM for that table. All rows inserted by transactions with XIDs older than this cutoff XID are guaranteed to have been frozen. Similarly, the datfrozenxid column of a database's pg_database row is a lower bound on the unfrozen XIDs appearing in that database — it is just the minimum of the per-table relfrozenxid values within the database. A convenient way to examine this information is to execute queries such as:
Routine Database Maintenance Tasks

```sql
SELECT c.oid::regclass as table_name,
       greatest(age(c.relfrozenxid),age(t.relfrozenxid)) as age
FROM pg_class c
LEFT JOIN pg_class t ON c.reltoastrelid = t.oid
WHERE c.relkind IN ('r', 'm');

SELECT datname, age(datfrozenxid) FROM pg_database;
```

The `age` column measures the number of transactions from the cutoff XID to the current transaction's XID.

VACUUM normally only scans pages that have been modified since the last vacuum, but `relfrozenxid` can only be advanced when every page of the table that might contain unfrozen XIDs is scanned. This happens when `relfrozenxid` is more than `vacuum_freeze_table_age` transactions old, when VACUUM's FREEZE option is used, or when all pages that are not already all-frozen happen to require vacuuming to remove dead row versions. When VACUUM scans every page in the table that is not already all-frozen, it should set `age(relfrozenxid)` to a value just a little more than the `vacuum_freeze_min_age` setting that was used (more by the number of transactions started since the VACUUM started). If no `relfrozenxid`-advancing VACUUM is issued on the table until `autovacuum_freeze_max_age` is reached, an autovacuum will soon be forced for the table.

If for some reason autovacuum fails to clear old XIDs from a table, the system will begin to emit warning messages like this when the database's oldest XIDs reach forty million transactions from the wraparound point:

```
WARNING:  database "mydb" must be vacuumed within 39985967 transactions
HINT:  To avoid a database shutdown, execute a database-wide VACUUM in that database.
```

(A manual VACUUM should fix the problem, as suggested by the hint; but note that the VACUUM must be performed by a superuser, else it will fail to process system catalogs and thus not be able to advance the database's `datfrozenxid`.) If these warnings are ignored, the system will shut down and refuse to start any new transactions once there are fewer than three million transactions left until wraparound:

```
ERROR:  database is not accepting commands to avoid wraparound data loss in database "mydb"
HINT:  Stop the postmaster and vacuum that database in single-user mode.
```

The three-million-transaction safety margin exists to let the administrator recover without data loss, by manually executing the required VACUUM commands. However, since the system will not execute commands once it has gone into the safety shutdown mode, the only way to do this is to stop the server and start the server in single-user mode to execute VACUUM. The shutdown mode is not enforced in single-user mode. See the postgres reference page for details about using single-user mode.

### 23.1.5.1. Multixacts and Wraparound

**Multixact IDs** are used to support row locking by multiple transactions. Since there is only limited space in a tuple header to store lock information, that information is encoded as a “multiple transaction ID”, or multixact ID for short, whenever there is more than one transaction concurrently locking a row. Information about which transaction IDs are included in any particular multixact ID is stored separately in the `pg_multixact` subdirectory, and only the multixact ID appears in the `xmax` field in the tuple header. Like transaction IDs, multixact IDs are implemented as a 32-bit counter and corresponding storage, all of which requires careful aging management, storage cleanup, and wraparound handling. There is a separate storage area which holds the list of members in each multixact, which also uses a 32-bit counter and which must also be managed.

Whenever VACUUM scans any part of a table, it will replace any multixact ID it encounters which is older than `vacuum_multixact_freeze_min_age` by a different value, which can be the zero value, a single transaction ID, or a newer multixact ID. For each table, `pg_class.relminmxid` stores the oldest possible multixact ID still appearing in any tuple of that table. If this value is older than `vacuum_multixact_freeze_table_age`, an aggressive vacuum is forced. As discussed in the previous section, an aggressive vacuum means that only those pages which are known to be all-frozen will be skipped. `mxid_age()` can be used on `pg_class.relminmxid` to find its age.
Aggressive VACUUM scans, regardless of what causes them, enable advancing the value for that table. Eventually, as all tables in all databases are scanned and their oldest multixact values are advanced, on-disk storage for older multixacts can be removed.

As a safety device, an aggressive vacuum scan will occur for any table whose multixact-age (see Section 23.1.5.1) is greater than autovacuum_multixact_freeze_max_age. Also, if the storage occupied by multixacts members exceeds 2GB, aggressive vacuum scans will occur more often for all tables, starting with those that have the oldest multixact-age. Both of these kinds of aggressive scans will occur even if autovacuum is nominally disabled.

23.1.6. The Autovacuum Daemon

Postgres Pro has an optional but highly recommended feature called autovacuum, whose purpose is to automate the execution of VACUUM and ANALYZE commands. When enabled, autovacuum checks for tables that have had a large number of inserted, updated or deleted tuples. These checks use the statistics collection facility; therefore, autovacuum cannot be used unless track_counts is set to true. In the default configuration, autovacuuming is enabled and the related configuration parameters are appropriately set.

The “autovacuum daemon” actually consists of multiple processes. There is a persistent daemon process, called the autovacuum launcher, which is in charge of starting autovacuum worker processes for all databases. The launcher will distribute the work across time, attempting to start one worker within each database every autovacuum_naptime seconds. (Therefore, if the installation has N databases, a new worker will be launched every autovacuum_naptime/N seconds.) A maximum of autovacuum_max_workers worker processes are allowed to run at the same time. If there are more than autovacuum_max_workers databases to be processed, the next database will be processed as soon as the first worker finishes. Each worker process will check each table within its database and execute VACUUM and/or ANALYZE as needed. log_autovacuum_min_duration can be set to monitor autovacuum workers' activity.

If several large tables all become eligible for vacuuming in a short amount of time, all autovacuum workers might become occupied with vacuuming those tables for a long period. This would result in other tables and databases not being vacuumed until a worker becomes available. There is no limit on how many workers might be in a single database, but workers do try to avoid repeating work that has already been done by other workers. Note that the number of running workers does not count towards max_connections or superuser_reserved_connections limits.

Tables whose relfrozenxid value is more than autovacuum_freeze_max_age transactions old are always vacuumed (this also applies to those tables whose freeze max age has been modified via storage parameters; see below). Otherwise, if the number of tuples obsoleted since the last VACUUM exceeds the “vacuum threshold”, the table is vacuumed. The vacuum threshold is defined as:

\[
\text{vacuum threshold} = \text{vacuum base threshold} + \text{vacuum scale factor} \times \text{number of tuples}
\]

where the vacuum base threshold is autovacuum_vacuum_threshold, the vacuum scale factor is autovacuum_vacuum_scale_factor, and the number of tuples is \( \text{pg_class}.\text{reltuples} \).

The table is also vacuumed if the number of tuples inserted since the last vacuum has exceeded the defined insert threshold, which is defined as:

\[
\text{vacuum insert threshold} = \text{vacuum base insert threshold} + \text{vacuum insert scale factor} \times \text{number of tuples}
\]

where the vacuum insert base threshold is autovacuum_vacuum_insert_threshold, and vacuum insert scale factor is autovacuum_vacuum_insert_scale_factor. Such vacuums may allow portions of the table to be marked as all visible and also allow tuples to be frozen, which can reduce the work required in subsequent vacuums. For tables which receive INSERT operations but no or almost no UPDATE/DELETE operations, it may be beneficial to lower the table's autovacuum_freeze_min_age as this may allow tuples to be frozen by earlier vacuums. The number of obsolete tuples and the number of inserted tuples are obtained from the statistics collector; it is a semi-accurate count updated by each UPDATE, DELETE and INSERT operation. (It is only semi-accurate because some information might be lost under heavy load.)
If the `relfrozenxid` value of the table is more than `vacuum_freeze_table_age` transactions old, an aggressive vacuum is performed to freeze old tuples and advance `relfrozenxid`; otherwise, only pages that have been modified since the last vacuum are scanned.

For analyze, a similar condition is used: the threshold, defined as:

\[
analyze \text{ threshold} = \text{analyze base threshold} + \text{analyze scale factor} \times \text{number of tuples}
\]

is compared to the total number of tuples inserted, updated, or deleted since the last `ANALYZE`.

Temporary tables cannot be accessed by autovacuum. Therefore, appropriate vacuum and analyze operations should be performed via session SQL commands.

The default thresholds and scale factors are taken from `postgresql.conf`, but it is possible to override them (and many other autovacuum control parameters) on a per-table basis; see `Storage Parameters` for more information. If a setting has been changed via a table’s storage parameters, that value is used when processing that table; otherwise the global settings are used. See Section 18.10 for more details on the global settings.

When multiple workers are running, the autovacuum cost delay parameters (see Section 18.4.4) are “balanced” among all the running workers, so that the total I/O impact on the system is the same regardless of the number of workers actually running. However, any workers processing tables whose `per-table autovacuum_vacuum_cost_delay` or `autovacuum_vacuum_cost_limit` storage parameters have been set are not considered in the balancing algorithm.

Autovacuum workers generally don’t block other commands. If a process attempts to acquire a lock that conflicts with the `SHARE UPDATE EXCLUSIVE` lock held by autovacuum, lock acquisition will interrupt the autovacuum. For conflicting lock modes, see Table 13.2. However, if the autovacuum is running to prevent transaction ID wraparound (i.e., the autovacuum query name in the `pg_stat_activity` view ends with `(to prevent wraparound)`), the autovacuum is not automatically interrupted.

### Warning

Regularly running commands that acquire locks conflicting with a `SHARE UPDATE EXCLUSIVE` lock (e.g., `ANALYZE`) can effectively prevent autovacuums from ever completing.

#### 23.2. Routine Reindexing

In some situations it is worthwhile to rebuild indexes periodically with the `REINDEX` command or a series of individual rebuilding steps.

B-tree index pages that have become completely empty are reclaimed for re-use. However, there is still a possibility of inefficient use of space: if all but a few index keys on a page have been deleted, the page remains allocated. Therefore, a usage pattern in which most, but not all, keys in each range are eventually deleted will see poor use of space. For such usage patterns, periodic reindexing is recommended.

The potential for bloat in non-B-tree indexes has not been well researched. It is a good idea to periodically monitor the index’s physical size when using any non-B-tree index type.

Also, for B-tree indexes, a freshly-constructed index is slightly faster to access than one that has been updated many times because logically adjacent pages are usually also physically adjacent in a newly built index. (This consideration does not apply to non-B-tree indexes.) It might be worthwhile to reindex periodically just to improve access speed.

`REINDEX` can be used safely and easily in all cases. This command requires an `ACCESS EXCLUSIVE` lock by default, hence it is often preferable to execute it with its `CONCURRENTLY` option, which requires only a `SHARE UPDATE EXCLUSIVE` lock.
23.3. Log File Maintenance

It is a good idea to save the database server’s log output somewhere, rather than just discarding it via /dev/null. The log output is invaluable when diagnosing problems. However, the log output tends to be voluminous (especially at higher debug levels) so you won’t want to save it indefinitely. You need to rotate the log files so that new log files are started and old ones removed after a reasonable period of time.

If you simply direct the stderr of postgres into a file, you will have log output, but the only way to truncate the log file is to stop and restart the server. This might be acceptable if you are using Postgres Pro in a development environment, but few production servers would find this behavior acceptable.

A better approach is to send the server’s stderr output to some type of log rotation program. There is a built-in log rotation facility, which you can use by setting the configuration parameter `logging_collector` to `true` in `postgresql.conf`. The control parameters for this program are described in Section 18.8.1. You can also use this approach to capture the log data in machine readable CSV (comma-separated values) format.

Alternatively, you might prefer to use an external log rotation program if you have one that you are already using with other server software. For example, the rotatelogs tool included in the Apache distribution can be used with Postgres Pro. One way to do this is to pipe the server’s stderr output to the desired program. If you start the server with `pg_ctl`, then stderr is already redirected to stdout, so you just need a pipe command, for example:

```
pg_ctl start | rotatelogs /var/log/pgsql_log 86400
```

You can combine these approaches by setting up logrotate to collect log files produced by Postgres Pro built-in logging collector. In this case, the logging collector defines the names and location of the log files, while logrotate periodically archives these files. When initiating log rotation, logrotate must ensure that the application sends further output to the new file. This is commonly done with a postrotate script that sends a `SIGHUP` signal to the application, which then reopens the log file. In Postgres Pro, you can run `pg_ctl` with the `logrotate` option instead. When the server receives this command, the server either switches to a new log file or reopens the existing file, depending on the logging configuration (see Section 18.8.1).

```
Note

When using static log file names, the server might fail to reopen the log file if the max open file limit is reached or a file table overflow occurs. In this case, log messages are sent to the old log file until a successful log rotation. If logrotate is configured to compress the log file and delete it, the server may lose the messages logged in this time frame. To avoid this issue, you can configure the logging collector to dynamically assign log file names and use a prerotate script to ignore open log files.
```

Another production-grade approach to managing log output is to send it to syslog and let syslog deal with file rotation. To do this, set the configuration parameter `log_destination` to `syslog` (to log to syslog only) in `postgresql.conf`. Then you can send a `SIGHUP` signal to the syslog daemon whenever you want to force it to start writing a new log file. If you want to automate log rotation, the logrotate program can be configured to work with log files from syslog.

On many systems, however, syslog is not very reliable, particularly with large log messages; it might truncate or drop messages just when you need them the most. Also, on Linux, syslog will flush each message to disk, yielding poor performance. (You can use a “–” at the start of the file name in the syslog configuration file to disable syncing.)

Note that all the solutions described above take care of starting new log files at configurable intervals, but they do not handle deletion of old, no-longer-useful log files. You will probably want to set up a batch job to periodically delete old log files. Another possibility is to configure the rotation program so that old log files are overwritten cyclically.
**pgBadger** is an external project that does sophisticated log file analysis. **check_postgres** provides Nagios alerts when important messages appear in the log files, as well as detection of many other extraordinary conditions.
Chapter 24. Backup and Restore

As with everything that contains valuable data, Postgres Pro databases should be backed up regularly. While the procedure is essentially simple, it is important to have a clear understanding of the underlying techniques and assumptions.

There are three fundamentally different approaches to backing up Postgres Pro data:

- SQL dump
- File system level backup
- Continuous archiving

Each has its own strengths and weaknesses; each is discussed in turn in the following sections.

24.1. SQL Dump

The idea behind this dump method is to generate a file with SQL commands that, when fed back to the server, will recreate the database in the same state as it was at the time of the dump. Postgres Pro provides the utility program pg_dump for this purpose. The basic usage of this command is:

```
pg_dump dbname > dumpfile
```

As you see, pg_dump writes its result to the standard output. We will see below how this can be useful.

While the above command creates a text file, pg_dump can create files in other formats that allow for parallelism and more fine-grained control of object restoration.

pg_dump is a regular Postgres Pro client application (albeit a particularly clever one). This means that you can perform this backup procedure from any remote host that has access to the database. But remember that pg_dump does not operate with special permissions. In particular, it must have read access to all tables that you want to back up, so in order to back up the entire database you almost always have to run it as a database superuser. (If you do not have sufficient privileges to back up the entire database, you can still back up portions of the database to which you do have access using options such as `-n schema` or `-t table`.)

To specify which database server pg_dump should contact, use the command line options `-h host` and `-p port`. The default host is the local host or whatever your `PGHOST` environment variable specifies. Similarly, the default port is indicated by the `PGPORT` environment variable or, failing that, by the compiled-in default. (Conveniently, the server will normally have the same compiled-in default.)

Like any other Postgres Pro client application, pg_dump will by default connect with the database user name that is equal to the current operating system user name. To override this, either specify the `-U` option or set the environment variable `PGUSER`. Remember that pg_dump connections are subject to the normal client authentication mechanisms (which are described in Chapter 19).

An important advantage of pg_dump over the other backup methods described later is that pg_dump's output can generally be re-loaded into newer versions of Postgres Pro, whereas file-level backups and continuous archiving are both extremely server-version-specific. pg_dump is also the only method that will work when transferring a database to a different machine architecture, such as going from a 32-bit to a 64-bit server.

Dumps created by pg_dump are internally consistent, meaning, the dump represents a snapshot of the database at the time pg_dump began running. pg_dump does not block other operations on the database while it is working. (Exceptions are those operations that need to operate with an exclusive lock, such as most forms of `ALTER TABLE`.)

24.1.1. Restoring the Dump

Text files created by pg_dump are intended to be read in by the psql program. The general command form to restore a dump is
psql dbname < dumpfile

where *dumpfile* is the file output by the pg_dump command. The database *dbname* will not be created by this command, so you must create it yourself from template0 before executing psql (e.g., with `createdb -T template0 dbname`). psql supports options similar to pg_dump for specifying the database server to connect to and the user name to use. See the psql reference page for more information. Non-text file dumps are restored using the pg_restore utility.

Before restoring an SQL dump, all the users who own objects or were granted permissions on objects in the dumped database must already exist. If they do not, the restore will fail to recreate the objects with the original ownership and/or permissions. (Sometimes this is what you want, but usually it is not.)

By default, the psql script will continue to execute after an SQL error is encountered. You might wish to run psql with the `ON_ERROR_STOP` variable set to alter that behavior and have psql exit with an exit status of 3 if an SQL error occurs:

```
psql --set ON_ERROR_STOP=on dbname < dumpfile
```

Either way, you will only have a partially restored database. Alternatively, you can specify that the whole dump should be restored as a single transaction, so the restore is either fully completed or fully rolled back. This mode can be specified by passing the `-1` or `--single-transaction` command-line options to psql. When using this mode, be aware that even a minor error can rollback a restore that has already run for many hours. However, that might still be preferable to manually cleaning up a complex database after a partially restored dump.

The ability of pg_dump and psql to write to or read from pipes makes it possible to dump a database directly from one server to another, for example:

```
pg_dump -h host1 dbname | psql -h host2 dbname
```

---

**Important**

The dumps produced by pg_dump are relative to template0. This means that any languages, procedures, etc. added via `template1` will also be dumped by pg_dump. As a result, when restoring, if you are using a customized `template1`, you must create the empty database from `template0`, as in the example above.

After restoring a backup, it is wise to run `ANALYZE` on each database so the query optimizer has useful statistics; see Section 23.1.3 and Section 23.1.6 for more information. For more advice on how to load large amounts of data into Postgres Pro efficiently, refer to Section 14.4.

---

### 24.1.2. Using pg_dumpall

pg_dump dumps only a single database at a time, and it does not dump information about roles or tablespaces (because those are cluster-wide rather than per-database). To support convenient dumping of the entire contents of a database cluster, the `pg_dumpall` program is provided. `pg_dumpall` backs up each database in a given cluster, and also preserves cluster-wide data such as role and tablespace definitions. The basic usage of this command is:

```
pg_dumpall > dumpfile
```

The resulting dump can be restored with psql:

```
psql -f dumpfile postgres
```

(Actually, you can specify any existing database name to start from, but if you are loading into an empty cluster then `postgres` should usually be used.) It is always necessary to have database superuser access when restoring a `pg_dumpall` dump, as that is required to restore the role and tablespace information. If you use tablespaces, make sure that the tablespace paths in the dump are appropriate for the new installation.
pg_dumpall works by emitting commands to re-create roles, tablespaces, and empty databases, then
invoking pg_dump for each database. This means that while each database will be internally consistent,
the snapshots of different databases are not synchronized.

Cluster-wide data can be dumped alone using the pg_dumpall --globals-only option. This is necessary
to fully backup the cluster if running the pg_dump command on individual databases.

24.1.3. Handling Large Databases

Some operating systems have maximum file size limits that cause problems when creating large pg_dump
output files. Fortunately, pg_dump can write to the standard output, so you can use standard Unix tools
to work around this potential problem. There are several possible methods:

Use compressed dumps. You can use your favorite compression program, for example gzip:

```bash
pg_dump dbname | gzip > filename.gz
```

Reload with:
```
gunzip -c filename.gz | psql dbname
```
or:
```
cat filename.gz | gunzip | psql dbname
```

Use split. The split command allows you to split the output into smaller files that are acceptable
in size to the underlying file system. For example, to make 2 gigabyte chunks:

```bash
pg_dump dbname | split -b 2G - filename
```

Reload with:
```
cat filename* | psql dbname
```

If using GNU split, it is possible to use it and gzip together:
```
pg_dump dbname | split -b 2G --filter='gzip > $FILE.gz'
```

It can be restored using zcat.

Use pg_dump’s custom dump format. If Postgres Pro was built on a system with the zlib
compression library installed, the custom dump format will compress data as it writes it to the output
file. This will produce dump file sizes similar to using gzip, but it has the added advantage that tables
can be restored selectively. The following command dumps a database using the custom dump format:

```bash
pg_dump -Fc dbname > filename
```

A custom-format dump is not a script for psql, but instead must be restored with pg_restore, for example:
```
pg_restore -d dbname filename
```

See the pg_dump and pg_restore reference pages for details.

For very large databases, you might need to combine split with one of the other two approaches.

Use pg_dump’s parallel dump feature. To speed up the dump of a large database, you can use
pg_dump’s parallel mode. This will dump multiple tables at the same time. You can control the degree of
parallelism with the -j parameter. Parallel dumps are only supported for the "directory" archive format.
```
pg_dump -j num -F d -f out.dir dbname
```

You can use pg_restore -j to restore a dump in parallel. This will work for any archive of either the
"custom" or the "directory" archive mode, whether or not it has been created with pg_dump -j.

24.2. File System Level Backup

An alternative backup strategy is to directly copy the files that Postgres Pro uses to store the data in the
database; Section 17.2 explains where these files are located. You can use whatever method you prefer
for doing file system backups; for example:
Backup and Restore

```
tar -cf backup.tar /usr/local/pgsql/data
```

There are two restrictions, however, which make this method impractical, or at least inferior to the pg_dump method:

1. The database server *must* be shut down in order to get a usable backup. Half-way measures such as disallowing all connections will *not* work (in part because tar and similar tools do not take an atomic snapshot of the state of the file system, but also because of internal buffering within the server). Information about stopping the server can be found in Section 17.5. Needless to say, you also need to shut down the server before restoring the data.

2. If you have dug into the details of the file system layout of the database, you might be tempted to try to back up or restore only certain individual tables or databases from their respective files or directories. This will *not* work because the information contained in these files is not usable without the commit log files, pg_xact/*, which contain the commit status of all transactions. A table file is only usable with this information. Of course it is also impossible to restore only a table and the associated pg_xact data because that would render all other tables in the database cluster useless. So file system backups only work for complete backup and restoration of an entire database cluster.

An alternative file-system backup approach is to make a “consistent snapshot” of the data directory, if the file system supports that functionality (and you are willing to trust that it is implemented correctly). The typical procedure is to make a “frozen snapshot” of the volume containing the database, then copy the whole data directory (not just parts, see above) from the snapshot to a backup device, then release the frozen snapshot. This will work even while the database server is running. However, a backup created in this way saves the database files in a state as if the database server was not properly shut down; therefore, when you start the database server on the backed-up data, it will think the previous server instance crashed and will replay the WAL log. This is not a problem; just be aware of it (and be sure to include the WAL files in your backup). You can perform a `CHECKPOINT` before taking the snapshot to reduce recovery time.

If your database is spread across multiple file systems, there might not be any way to obtain exactly-simultaneous frozen snapshots of all the volumes. For example, if your data files and WAL log are on different disks, or if tablespaces are on different file systems, it might not be possible to use snapshot backup because the snapshots *must* be simultaneous. Read your file system documentation very carefully before trusting the consistent-snapshot technique in such situations.

If simultaneous snapshots are not possible, one option is to shut down the database server long enough to establish all the frozen snapshots. Another option is to perform a continuous archiving base backup (Section 24.3.2) because such backups are immune to file system changes during the backup. This requires enabling continuous archiving just during the backup process; restore is done using continuous archive recovery (Section 24.3.4).

Another option is to use rsync to perform a file system backup. This is done by first running rsync while the database server is running, then shutting down the database server long enough to do an rsync --checksum. (--checksum is necessary because rsync only has file modification-time granularity of one second.) The second rsync will be quicker than the first, because it has relatively little data to transfer, and the end result will be consistent because the server was down. This method allows a file system backup to be performed with minimal downtime.

Note that a file system backup will typically be larger than an SQL dump. (pg_dump does not need to dump the contents of indexes for example, just the commands to recreate them.) However, taking a file system backup might be faster.

### 24.3. Continuous Archiving and Point-in-Time Recovery (PITR)

At all times, Postgres Pro maintains a write ahead log (WAL) in the pg_wal/ subdirectory of the cluster's data directory. The log records every change made to the database’s data files. This log exists primarily for crash-safety purposes: if the system crashes, the database can be restored to consistency.
by “replaying” the log entries made since the last checkpoint. However, the existence of the log makes it possible to use a third strategy for backing up databases: we can combine a file-system-level backup with backup of the WAL files. If recovery is needed, we restore the file system backup and then replay from the backed-up WAL files to bring the system to a current state. This approach is more complex to administer than either of the previous approaches, but it has some significant benefits:

- We do not need a perfectly consistent file system backup as the starting point. Any internal inconsistency in the backup will be corrected by log replay (this is not significantly different from what happens during crash recovery). So we do not need a file system snapshot capability, just tar or a similar archiving tool.

- Since we can combine an indefinitely long sequence of WAL files for replay, continuous backup can be achieved simply by continuing to archive the WAL files. This is particularly valuable for large databases, where it might not be convenient to take a full backup frequently.

- It is not necessary to replay the WAL entries all the way to the end. We could stop the replay at any point and have a consistent snapshot of the database as it was at that time. Thus, this technique supports point-in-time recovery: it is possible to restore the database to its state at any time since your base backup was taken.

- If we continuously feed the series of WAL files to another machine that has been loaded with the same base backup file, we have a warm standby system: at any point we can bring up the second machine and it will have a nearly-current copy of the database.

Note

pg_dump and pg_dumpall do not produce file-system-level backups and cannot be used as part of a continuous-archiving solution. Such dumps are logical and do not contain enough information to be used by WAL replay.

As with the plain file-system-backup technique, this method can only support restoration of an entire database cluster, not a subset. Also, it requires a lot of archival storage: the base backup might be bulky, and a busy system will generate many megabytes of WAL traffic that have to be archived. Still, it is the preferred backup technique in many situations where high reliability is needed.

To recover successfully using continuous archiving (also called “online backup” by many database vendors), you need a continuous sequence of archived WAL files that extends back at least as far as the start time of your backup. So to get started, you should set up and test your procedure for archiving WAL files before you take your first base backup. Accordingly, we first discuss the mechanics of archiving WAL files.

### 24.3.1. Setting Up WAL Archiving

In an abstract sense, a running Postgres Pro system produces an indefinitely long sequence of WAL records. The system physically divides this sequence into WAL segment files, which are normally 16MB apiece (although the segment size can be altered during initdb). The segment files are given numeric names that reflect their position in the abstract WAL sequence. When not using WAL archiving, the system normally creates just a few segment files and then “recycles” them by renaming no-longer-needed segment files to higher segment numbers. It’s assumed that segment files whose contents precede the last checkpoint are no longer of interest and can be recycled.

When archiving WAL data, we need to capture the contents of each segment file once it is filled, and save that data somewhere before the segment file is recycled for reuse. Depending on the application and the available hardware, there could be many different ways of “saving the data somewhere”: we could copy the segment files to an NFS-mounted directory on another machine, write them onto a tape drive (ensuring that you have a way of identifying the original name of each file), or batch them together and burn them onto CDs, or something else entirely. To provide the database administrator with flexibility, Postgres Pro tries not to make any assumptions about how the archiving will be done. Instead, Postgres Pro lets the administrator specify a shell command to be executed to copy a completed segment file to
Backup and Restore

wherever it needs to go. The command could be as simple as a `cp`, or it could invoke a complex shell script — it's all up to you.

To enable WAL archiving, set the `wal_level` configuration parameter to `replica` or higher, `archive_mode` to `on`, and specify the shell command to use in the `archive_command` configuration parameter. In practice these settings will always be placed in the `postgresql.conf` file. In `archive_command`, `%p` is replaced by the path name of the file to archive, while `%f` is replaced by only the file name. (The path name is relative to the current working directory, i.e., the cluster's data directory.) Use `%%` if you need to embed an actual `%` character in the command. The simplest useful command is something like:

```plaintext
archive_command = 'test ! -f /mnt/server/archivedir/%f && cp %p /mnt/server/archivedir/%f'  # Unix
archive_command = 'copy "%p" "C:\\server\\archivedir\\%f"'  # Windows
```

which will copy archivable WAL segments to the directory `/mnt/server/archivedir`. (This is an example, not a recommendation, and might not work on all platforms.) After the `%p` and `%f` parameters have been replaced, the actual command executed might look like this:

```plaintext
test ! -f /mnt/server/archivedir/00000001000000A900000065 & & cp pg_wal/00000001000000A900000065 /mnt/server/archivedir/00000001000000A900000065
```

A similar command will be generated for each new file to be archived.

The archive command will be executed under the ownership of the same user that the Postgres Pro server is running as. Since the series of WAL files being archived contains effectively everything in your database, you will want to be sure that the archived data is protected from prying eyes; for example, archive into a directory that does not have group or world read access.

It is important that the archive command return zero exit status if and only if it succeeds. Upon getting a zero result, Postgres Pro will assume that the file has been successfully archived, and will remove or recycle it. However, a nonzero status tells Postgres Pro that the file was not archived; it will try again periodically until it succeeds.

When the archive command is terminated by a signal (other than SIGTERM that is used as part of a server shutdown) or an error by the shell with an exit status greater than 125 (such as command not found), the archiver process aborts and gets restarted by the postmaster. In such cases, the failure is not reported in `pg_stat_archiver`.

The archive command should generally be designed to refuse to overwrite any pre-existing archive file. This is an important safety feature to preserve the integrity of your archive in case of administrator error (such as sending the output of two different servers to the same archive directory).

It is advisable to test your proposed archive command to ensure that it indeed does not overwrite an existing file, and that it returns nonzero status in this case. The example command above for Unix ensures this by including a separate `test` step. On some Unix platforms, `cp` has switches such as `-i` that can be used to do the same thing less verbosely, but you should not rely on these without verifying that the right exit status is returned. (In particular, GNU `cp` will return status zero when `-i` is used and the target file already exists, which is not the desired behavior.)

While designing your archiving setup, consider what will happen if the archive command fails repeatedly because some aspect requires operator intervention or the archive runs out of space. For example, this could occur if you write to tape without an autochanger; when the tape fills, nothing further can be archived until the tape is swapped. You should ensure that any error condition or request to a human operator is reported appropriately so that the situation can be resolved reasonably quickly. The `pg_wal` directory will continue to fill with WAL segment files until the situation is resolved. (If the file system containing `pg_wal` fills up, Postgres Pro will do a PANIC shutdown. No committed transactions will be lost, but the database will remain offline until you free some space.)

The speed of the archiving command is unimportant as long as it can keep up with the average rate at which your server generates WAL data. Normal operation continues even if the archiving process fails.
a little behind. If archiving falls significantly behind, this will increase the amount of data that would be lost in the event of a disaster. It will also mean that the pg_wal/ directory will contain large numbers of not-yet-archived segment files, which could eventually exceed available disk space. You are advised to monitor the archiving process to ensure that it is working as you intend.

In writing your archive command, you should assume that the file names to be archived can be up to 64 characters long and can contain any combination of ASCII letters, digits, and dots. It is not necessary to preserve the original relative path (\%p) but it is necessary to preserve the file name (\%f).

Note that although WAL archiving will allow you to restore any modifications made to the data in your Postgres Pro database, it will not restore changes made to configuration files (that is, postgresql.conf, pg_hba.conf and pg_ident.conf), since those are edited manually rather than through SQL operations. You might wish to keep the configuration files in a location that will be backed up by your regular file system backup procedures. See Section 18.2 for how to relocate the configuration files.

The archive command is only invoked on completed WAL segments. Hence, if your server generates only little WAL traffic (or has slack periods where it does so), there could be a long delay between the completion of a transaction and its safe recording in archive storage. To put a limit on how old unarchived data can be, you can set archive_timeout to force the server to switch to a new WAL segment file at least that often. Note that archived files that are archived early due to a forced switch are still the same length as completely full files. It is therefore unwise to set a very short archive_timeout — it will bloat your archive storage. archive_timeout settings of a minute or so are usually reasonable.

Also, you can force a segment switch manually with pg_switch_wal if you want to ensure that a just-finished transaction is archived as soon as possible. Other utility functions related to WAL management are listed in Table 9.87.

When wal_level is minimal some SQL commands are optimized to avoid WAL logging, as described in Section 14.4.7. If archiving or streaming replication were turned on during execution of one of these statements, WAL would not contain enough information for archive recovery. (Crash recovery is unaffected.) For this reason, wal_level can only be changed at server start. However, archive_command can be changed with a configuration file reload. If you wish to temporarily stop archiving, one way to do it is to set archive_timeout to a value that would force the server to switch to a new WAL segment file at least that often. This will cause WAL files to accumulate in pg_wal/ until a working archive_command is re-established.

### 24.3.2. Making a Base Backup

The easiest way to perform a base backup is to use the pg_basebackup tool. It can create a base backup either as regular files or as a tar archive. If more flexibility than pg_basebackup can provide is required, you can also make a base backup using the low level API (see Section 24.3.3).

It is not necessary to be concerned about the amount of time it takes to make a base backup. However, if you normally run the server with full_page_writes disabled, you might notice a drop in performance while the backup runs since full_page_writes is effectively forced on during backup mode.

To make use of the backup, you will need to keep all the WAL segment files generated during and after the file system backup. To aid you in doing this, the backup process generates a backup history file that is immediately stored into the WAL archive area. This file is named after the first WAL segment file that you need for the file system backup. For example, if the starting WAL file is 0000000100001234000055CD the backup history file will be named something like 0000000100001234000055CD.007C9330.backup. (The second part of the file name stands for an exact position within the WAL file, and can ordinarily be ignored.) Once you have safely archived the file system backup and the WAL segment files used during the backup (as specified in the backup history file), all archived WAL segments with names numerically less are no longer needed to recover the file system backup and can be deleted. However, you should consider keeping several backup sets to be absolutely certain that you can recover your data.

The backup history file is just a small text file. It contains the label string you gave to pg_basebackup, as well as the starting and ending times and WAL segments of the backup. If you used the label to identify the associated dump file, then the archived history file is enough to tell you which dump file to restore.
Since you have to keep around all the archived WAL files back to your last base backup, the interval between base backups should usually be chosen based on how much storage you want to expend on archived WAL files. You should also consider how long you are prepared to spend recovering, if recovery should be necessary — the system will have to replay all those WAL segments, and that could take awhile if it has been a long time since the last base backup.

### 24.3.3. Making a Base Backup Using the Low Level API

The procedure for making a base backup using the low level APIs contains a few more steps than the `pg_basebackup` method, but is relatively simple. It is very important that these steps are executed in sequence, and that the success of a step is verified before proceeding to the next step.

Low level base backups can be made in a non-exclusive or an exclusive way. The non-exclusive method is recommended and the exclusive one is deprecated and will eventually be removed.

#### 24.3.3.1. Making a Non-Exclusive Low-Level Backup

A non-exclusive low level backup is one that allows other concurrent backups to be running (both those started using the same backup API and those started using `pg_basebackup`).

1. Ensure that WAL archiving is enabled and working.
2. Connect to the server (it does not matter which database) as a user with rights to run `pg_start_backup` (superuser, or a user who has been granted EXECUTE on the function) and issue the command:

   ```sql
   SELECT pg_start_backup('label', false, false);
   ```

   where `label` is any string you want to use to uniquely identify this backup operation. The connection calling `pg_start_backup` must be maintained until the end of the backup, or the backup will be automatically aborted.

   By default, `pg_start_backup` can take a long time to finish. This is because it performs a checkpoint, and the I/O required for the checkpoint will be spread out over a significant period of time, by default half your inter-checkpoint interval (see the configuration parameter `checkpoint_completion_target`). This is usually what you want, because it minimizes the impact on query processing. If you want to start the backup as soon as possible, change the second parameter to `true`, which will issue an immediate checkpoint using as much I/O as available.

   The third parameter being `false` tells `pg_start_backup` to initiate a non-exclusive base backup.

3. Perform the backup, using any convenient file-system-backup tool such as tar or cpio (not `pg_dump` or `pg_dumpall`). It is neither necessary nor desirable to stop normal operation of the database while you do this. See Section 24.3.3.3 for things to consider during this backup.

4. In the same connection as before, issue the command:

   ```sql
   SELECT * FROM pg_stop_backup(false, true);
   ```

   This terminates backup mode. On a primary, it also performs an automatic switch to the next WAL segment. On a standby, it is not possible to automatically switch WAL segments, so you may wish to run `pg_switch_wal` on the primary to perform a manual switch. The reason for the switch is to arrange for the last WAL segment file written during the backup interval to be ready to archive.

   The `pg_stop_backup` will return one row with three values. The second of these fields should be written to a file named `backup_label` in the root directory of the backup. The third field should be written to a file named `tablespace_map` unless the field is empty. These files are vital to the backup working and must be written byte for byte without modification, which may require opening the file in binary mode.

5. Once the WAL segment files active during the backup are archived, you are done. The file identified by `pg_stop_backup`'s first return value is the last segment that is required to form a complete set of backup files. On a primary, if `archive_mode` is enabled and the `wait_for_archive` parameter is `true`, `pg_stop_backup` does not return until the last segment has been archived. On a standby,
Backup and Restore

archive_mode must be always in order for pg_stop_backup to wait. Archiving of these files happens automatically since you have already configured archive_command. In most cases this happens quickly, but you are advised to monitor your archive system to ensure there are no delays. If the archive process has fallen behind because of failures of the archive command, it will keep retrying until the archive succeeds and the backup is complete. If you wish to place a time limit on the execution of pg_stop_backup, set an appropriate statement_timeout value, but make note that if pg_stop_backup terminates because of this your backup may not be valid.
